Statistical analysis. All calculations were performed with the True Epistat program (Epistat Services, Round Rock, Tex.) on an IBM 386 personal computer (IBM Corporation, Boca Raton, Fla.). Two-sample comparisons were performed with Student's t test for inde-

pendent samples. One-way analysis of variance was used for comparison of more than two independent samples. Homogeneity of variance was assessed with Bartlett's test. Multiple comparisons were performed with the Newman-Keuls multiple range test.

Results

Cell density. Stromal cells were added at densities of 5×10^3 to 10^5 per well and cultured in serum-containing media. A linear relationship was noted between densities of 10^4 to 10^5 cells per well and radioisotope incorporation, with the least variance noted at 5×10^4 cells per well (data not shown). This density was thus chosen for the majority of experiments.

Effect of insulin. As insulin is a known progression factor for fibroblasts in supraphysiologic doses, an attempt was made to determine the dose response of endometrial stromal cells to insulin in a competence factor–containing medium. Cells were plated at 5×10^4 per well in RPMI 1640 with 10% fetal bovine serum. The addition of 10 ng/ml to 1 μg/ml insulin resulted in significant increases in thymidine incorporation ($p = 0.0005$), as seen in Fig. 1.

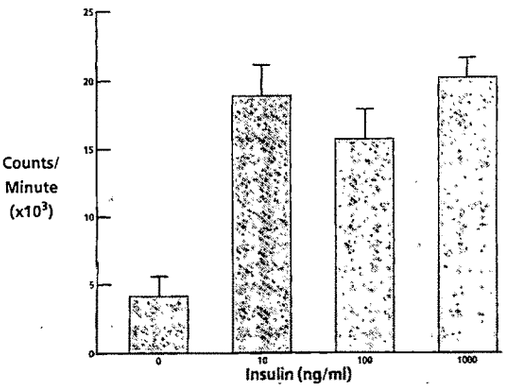

Fig. 1. Effect of addition of insulin (10, 100, and 1000 ng/ml) to serum-containing media on stromal cell proliferation as measured by [³H]thymidine incorporation (mean ± SEM in counts per minute). Cells were harvested after 48 hours of plating.

Effect of macrophage-conditioned medium. Stromal cultures of 10^4 cells per well were treated with serum-free media with or without 10% macrophage-conditioned medium from a variety of sources (Fig. 2). An increase in thymidine incorporation was noted in each of the macrophage-conditioned medium–treated samples, and all differed significantly from cells not exposed to macrophage-conditioned medium ($p = 0.0076$).

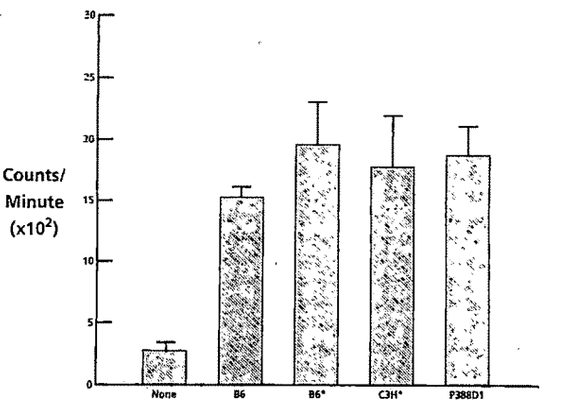

Fig. 2. Effect of addition of 10% macrophage-conditioned media on stromal cell proliferation as measured by [³H]thymidine incorporation (mean ± SEM in counts per minute). Cells were harvested 48 hours after plating. *None*, No macrophage-conditioned medium supplementation; *B6*, macrophage-conditioned medium from resident macrophages of C57BL/6J mice; *B6**, macrophage-conditioned medium from peptone-stimulated macrophages of C57BL/6J mice; *C3H**, macrophage-conditioned medium from peptone-stimulated macrophages of C3H/Hej mice; *P388D$_1$*, macrophage-conditioned medium from P388D$_1$ murine cell line.

To determine the precise effect of macrophage-conditioned medium, radioisotope incorporation was assessed in the presence of two culture media: one containing a known competence factor but lacking a progression factor (RPMI 1640 plus 10% fetal bovine serum) and one containing a known progression factor but lacking a competence factor (Nutridoma). Cells were then cultured at 5×10^4 per well. The results can be seen in Fig. 3. In the presence of serum-containing media without insulin, macrophage-conditioned medium failed to significantly affect proliferation. However, with the serum-free media with insulin, macrophage-conditioned medium significantly increased cell proliferation ($p = 0.00007$). Thus macrophage-conditioned medium is acting as a competence factor to promote endometrial cell growth. Finally, in a serum-free medium with insulin added, the presence or absence of macrophage-conditioned medium has no effect as thymidine incorporation is stimulated in either case.

Timing of addition of macrophage-conditioned medium. To assess whether the effect of macrophage-conditioned medium as a competence factor was acting to enhance initial cell survival or attachment or whether it was truly functioning to condition cells to respond to progression factor, addition of macrophage-conditioned medium was performed 24 hours after initial cell plating. Again the addition of macrophage-conditioned medium to the serum-free medium with insulin resulted in a significant increase in [³H]thymidine incorporation ($p = 0.02$) (Fig. 4).

Effect of estrogen. To assess the role of estrogen in endometrial stromal proliferation, cells were cultured

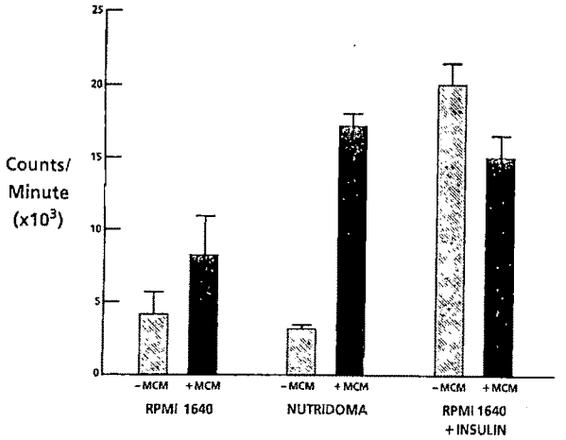

Fig. 3. Effect of addition of 10% macrophage-conditioned media on stromal cell proliferation as measured by [^{3}H]thymidine incorporation (mean ± SEM in counts per minute). *RPMI 1640*, Media containing competence factor with no progression factor; *Nutridoma*, media containing progression factor with no competence factor; *RPMI 1640 + insulin*, media containing competence factor with progression factor added (insulin, 1 μg/ml); *−MCM*, no macrophage-conditioned medium supplementation; *+MCM*, supplementation of culture medium with 10% macrophage-conditioned medium.

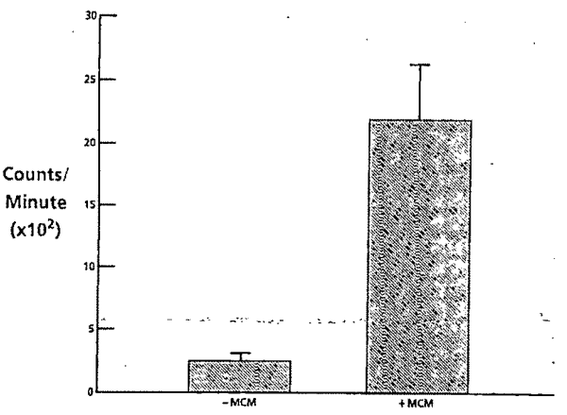

Fig. 4. Effect of addition of 10% macrophage-conditioned media on stromal cell proliferation as measured by [^{3}H]thymidine incorporation (mean ± SEM in counts per minute). Cells were cultured in Nutridoma (serum-free, insulin-containing) media for 24 hours before supplementation. Cells were harvested 72 hours after plating.

at 5×10^4 per well in insulin-free, serum-containing media with increasing concentrations of estradiol (Fig. 5). The addition of estrogen clearly increased thymidine incorporation ($p = 0.0009$), with maximal effect seen at 10^{-10} to 10^{-12} mol/L. Thus estradiol seems to complement serum (and act as a progression factor) in affecting stromal cell growth.

Conversely, when cells were cultured in a serum-free medium with insulin, estrogen had no affect on proliferation (Fig. 6). When 10% macrophage-conditioned

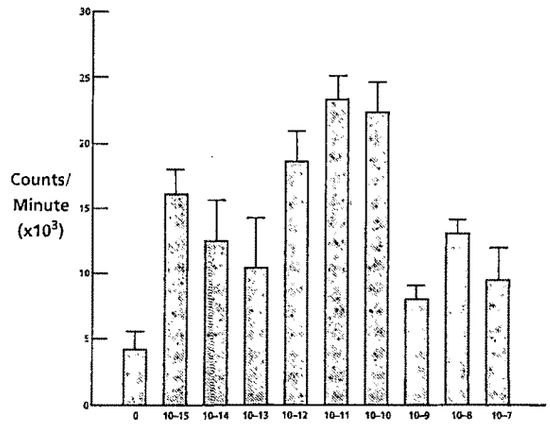

Fig. 5. Effect of addition of estradiol on stromal cell proliferation as measured by [^{3}H]thymidine incorporation (mean ± SEM in counts per minute). Cells were cultured in RPMI 1640 with 10% fetal bovine serum. Cells were harvested after 48 hours of plating.

medium was added to the serum-free medium with insulin, increased proliferation was noted for all samples, and estradiol failed to increase proliferation above that of the non-estradiol-treated control (Fig. 7). Thus estradiol performs the same function as insulin in enhancing stromal cell growth and demonstrates no additive or synergistic response.

Comment

The association between endometriosis and peritoneal macrophages has been recognized since Haney et al.[1] first reported an increase in macrophages in infertile women with the disorder. Subsequent studies have confirmed these findings and have demonstrated an increased level of activation[2] and increased membrane capping.[10] However, this association has not gone uncontested. Olive et al.[11] found an increase in peritoneal macrophage number to be associated with otherwise unexplained infertility, with no relationship between endometriosis and cell number. Hill et al.[12] also stated that the increase in macrophage number seen in infertile women with endometriosis was also found in women with unexplained infertility. Thus the presence of activated macrophages in increased number in endometriosis patients may be a function more of their infertility than of their implants.

Nevertheless, the hypothesis persists that ectopic endometrium incites an intraperitoneal inflammatory response, resulting in recruitment and differentiation of peritoneal macrophages. Indeed, peritoneal fluid lysozyme levels confirm a localized intraperitoneal inflammation in these women,[3] but a cause-and-effect relationship between implants and inflammatory cells has never been demonstrated. Recently a longitudinal

study[4] in the rabbit model evaluated the effect of ectopic endometrial implants on peritoneal macrophage number and function. The researchers were unable to demonstrate any effect of the implants on phagocytic cells, suggesting the above theory is in error. Additional studies are currently being conducted in an attempt to ensure that this lack of response is not species specific.

A more intriguing concept is the reverse—that a primary abnormality of peritoneal macrophages results in the promotion of growth of ectopic endometrium.[10] It has been well demonstrated that macrophages secrete growth factors that enhance fibroblast growth and proliferation.[5,6] These factors, cumulatively referred to as macrophage-derived growth factors, have been shown to be distinct from interleukin-1,[13] and may well be composed, at least partially, of platelet-derived growth factor[14] and fibroblast growth factor.[15]

The proliferation process has been studied extensively in the fibroblast. It appears that two types of growth factors are required to create a proliferative response in these cells: a competence factor, which confers on the cell the ability to respond to specific mitogens, and a progression factor, which causes a "competent" cell to progress through the G_1 phase to the S phase of cell growth.[16] Table I provides a partial listing of the substances identified as competence factors or progression factors in the fibroblast. Whereas it is likely that most mesothelium responds in a similar manner, to date this has been inadequately investigated.

Macrophage-derived growth factors function as competence factors in the fibroblast. Evidence presented here indicates a similar role for these growth factors in endometrial stroma. The ability to stimulate stromal growth in the presence of a known progression factor (insulin) in serum-free media suggests that macrophage-derived growth factors can substitute for serum in this competence-producing capacity. Furthermore, the inability of macrophage-conditioned medium to interact with serum in an insulin-free medium to produce cell growth suggests a lack of macrophage progression factor activity. Thus it seems that macrophage-derived growth factor should more appropriately be called macrophage-derived competence factor, a term previously suggested.[17]

Table I. Growth factors in the fibroblast

Competence factor	*Progression factor*
Serum	Endometrial growth factor
Platelet-derived growth factor	Somatomedin C
Fibroblast growth factor	Insulin
Macrophage-derived growth factor	Platelet-poor plasma

The role of estrogen as an endometrial stromal cell mitogen has been well recognized but poorly characterized. Initial studies by Kirk et al.[18] demonstrated an increase in stromal cell growth with 10^{-8} mol/L estradiol in a serum-containing medium. However, Casimiri et al.,[19] using similar conditions, failed to demonstrate any mitogenic effect of estradiol in culture. To further confuse the issue, Fleming and Gurpide[20] showed an inhibition of stromal cell growth with 10^{-8} to 10^{-9} mol/L estradiol in serum- and insulin-containing media. Finally, Irwin et al.[21] recently claimed no mitogenic effect of estrogen in the presence of insulin and serum, yet showed an increase in cell proliferation when estradiol and progesterone were added to the culture simultaneously.

Our studies suggest that estradiol can indeed stimulate endometrial stromal proliferation, but only under specific conditions. Estradiol appears to function as a progression factor in these cells and thus will fail to promote growth in the absence of cell exposure to a competence factor. In addition, estrogen and insulin (and presumably insulin-like growth factors) produce the same progression effect; thus the presence of insulin in culture will eliminate any apparent mitogenic effect of estrogen. Only in otherwise progression factor–free media will growth be apparent after the addition of estrogen.

These facts lead to an intriguing hypothesis for the pathogenesis of endometriosis. Reflux menstruation appears to lead to viable endometrial cells in the peritoneal cavity in the majority of women.[22, 23] However, specific conditions may be required for the tissue to implant and grow. It may well be that the transplanted endometrium fails to develop in the absence of sufficient competence or progression growth factor. However, in women with enhanced macrophage-derived growth factor secretion and relative hyperestrogenism, conditions may be optimal for endometrial implantation and growth. Previous findings of increased macrophage-derived growth factor in the peritoneal fluid of women with endometriosis,[7] as well as the apparent efficacy of hypoestrogenism in combating the disease,[24] make this theory compelling. We believe these findings clearly justify further investigation into these mechanisms as a means of regulating ectopic endometrial cell growth.

Astrocytes within the hypothalamic arcuate nucleus contain estrogen-sensitive peroxidase, bind fluorescein-conjugated estradiol, and may mediate synaptic plasticity in the rat

David L. Keefe, MD,[a] David S. Michelson,[a] S.H. Lee, MD,[b] and Frederick Naftolin, MD, DPhil[a]

New Haven, Connecticut

Estrogen treatment induces synaptic plasticity accompanied by damaged structures and aggregates of peroxidase in astrocytes in the hypothalamic arcuate nucleus of the rat. Synaptic plasticity also occurs within the arcuate nucleus after physiologic surges of estrogen. Although the function of estrogen-induced peroxidase is unclear at present, in other systems peroxidase can generate free radicals by catalyzing the oxidation of some molecules, including estrogen. Because free radicals underlie remodeling in a number of tissues, estrogen-induced free radicals could mediate synaptic remodeling within the arcuate nucleus. Although they contain estrogen-inducible peroxidase, astrocytes do not contain estrogen receptors as measured by conventional techniques, suggesting that estrogen-inducible peroxidase arises from some novel mechanism. Estrogen could induce peroxidase within receptor-deficient astrocytes by binding to receptors in neurons and stimulating the release of some factor that interacts with astrocytes. Alternatively, estrogen could act directly on astrocytes in the absence of estrogen receptors. Although astrocytes in the hypothalamus of the rat do not contain classical nuclear estrogen receptors, they do bind fluorescein-conjugated estradiol in extranuclear sites. The distribution of fluorescein-conjugated estradiol binding within the hypothalamus overlaps that of peroxidase-rich astrocytes, and double labeling reveals many cells with the stellate morphology of astrocytes, containing both peroxidase and fluorescein-conjugated estradiol binding. However, because peroxidase and fluorescein-conjugated estradiol always occupy different compartments of the cell, the fluorescein-conjugated estradiol is not binding to peroxidase.
(Am J Obstet Gynecol 1991;164:959-66.)

Key words: Astrocytes, estrogen, peroxidase, synaptic plasticity, hypothalamus

Twelve years ago at the One Hundred and First Annual Meeting of the American Gynecological Society meeting Naftolin and Brawer[1] summarized their work on the effects of estrogen in permanently organizing the reproductive brain of the newborn rat during the so called "critical period." They showed that in the male brain androgens are converted to estrogen by aromatase, rendering the male unable to have cyclic gonadotropin release. In the female, the majority of the estrogen made by the ovaries and placenta is bound stoichiometrically to circulating α-fetoprotein and does not enter the brain. In the absence of high levels of estrogen within the central nervous system during the critical period, cyclic gonadotropin release develops in the female as an adult. These studies established the central role of estrogen in organizing the brain of the newborn rat.

The effects of estrogen on the reproductive brain are not restricted to the newborn period. A single large dose of estrogen given to a cycling adult female rat induces persistent vaginal estrus characterized by hypothalamic anovulation with proestrus levels of estrogen and polycystic ovaries.[1-3] Estrogen given continuously at a low level also induces persistent estrus.[4] We now believe that the persistent estrus state that spontaneously arises in middle-aged rats results from the effects of the repeated estrogen surges during the ovarian cycle on the central nervous system.[3] This seems especially likely because estrogen antagonists such as

progesterone[5] and pseudopregnancy-pregnancy[5, 6] delay the appearance of senescent constant estrus.

Estrogen induces a tonic pattern of gonadotropin release by disrupting the estrogen-sensitive positive feedback mechanism

The anovulation of naturally or induced persistent estrus rats arises from disruption of the luteinizing hormone–releasing hormone (LH-RH) surge that normally occurs in response to acutely rising levels of estrogen. The same doses of estrogen given acutely to young and aged oophorectomized female rats result in markedly different patterns of LH release[6, 7]: the young, oophorectomized rat responds to estrogen with a robust LH surge. However, with age the LH surge mechanism becomes progressively refractory to triggering by estrogen. Transplantation of ovaries from young into aging female rats does not reverse the anovulatory state, whereas ovaries transplanted from aged into young female rats still can ovulate.[7] These and other related studies suggest that chronic exposure to estrogen alters the sensitivity of the LH-RH surge mechanism to acute administration of estrogen, and that the locus of estrogen's action is in the brain.

The arcuate nucleus of the rat hypothalamus provides an excellent model system for study of estrogen actions on gonadotropin release

Our research focuses on uncovering the cellular and molecular mechanisms involved in estrogen's effects on the hypothalamus. We use the rat model for a number of scientific and logistical reasons. In the rat, areas of the hypothalamus involved in the control of gonadotropin release are separated from each other; LH-RH neurons reside in the preoptic area, whereas many estrogen-sensitive neurons reside in the arcuate nucleus. This enables surgical isolation or dissection of specific nuclei so that they can be studied in great detail. We have focused on the arcuate nucleus of the hypothalamus because: (1) the LH-RH neurons do not bind estrogen, suggesting that estrogen influences LH-RH release indirectly by acting on other neurons,[8] (2) many neurons within the arcuate nucleus contain estrogen receptors[9] and some arcuate nucleus neurons synapse directly on LH-RH neurons[10] in the preoptic area, and (3) studies that use electrolytic lesions, knife cuts, and electrophysiologic stimulation and recording have shown a central role for the arcuate nucleus in mediating estrogen's effects on LH-RH release.[11]

Estrogen influences the morphology of both neurons and neuroglia within the arcuate nucleus

Before discussing further our findings on estrogen actions in the arcuate nucleus, it is helpful to review some fundamental concepts of neuroanatomy. The cellular makeup of the brain consists of two broad classes of cells—neurons and neuroglia.[18] Neurons make synapses with each other where electrical signals in the form of changes in the electrical potential across the neuron's plasma membrane are converted to chemical signals by release of neurotransmitters.[12] These synapses can be identified and counted under the electron microscope. Neuroglial cells have been much less studied than neurons, although they outnumber neurons 10:1 in the brain.[13] Neuroglia formerly were thought of as inactive support cells, but now we know that they can interact with neurons and carry out many important functions on their own. For example, neuroglia can stabilize brain functions by regulating extracellular potassium and hydrogen concentrations,[14, 15] protect brain cells by taking up excess excitatory neurotransmitters such as glutamate,[15] and mold the brain by guiding the migration of neurons during development.[16] In addition, because the foot processes from a single neuroglial cell can envelope and regulate the synaptic environments of widely separated neurons, neuroglial cells may contribute to the synchronization of widely dispersed neurons within the brain.[14, 18] Estrogen affects the morphology of both neurons and neuroglia within the arcuate nucleus.

Estrogen induces synaptic plasticity within the arcuate nucleus

Although estrogen influences many aspects of neuronal morphology, perhaps the most important action of estrogen is on synapses. In adult females estrogen given as an injection or as physiologic surges alters the number of synapses between axons and cell bodies (axosomatic) and between axons and dendrites (axodendritic) within the arcuate nucleus.[17] The number of synapses counted in electron micrographs taken from the arcuate nucleus is decreased by 30% at 8 weeks after a single dose of estrogen. By 32 weeks after estrogen treatment the number of synapses returns to baseline. Careful inspection of electron micrographs of the arcuate nucleus from estrogen-treated rats also shows evidence of synaptic damage, such as degenerating nerve fibers and activated microglia, which appear to be phagocytizing degenerating synaptic boutons.[1-3] Another kind of neuroglia, called astrocytes, also appear to be activated and will be discussed later.

The number of synapses within the arcuate nucleus also varies during physiologic surges of estrogen.[19] The number of synapses counted in the arcuate nucleus of rats killed on estrus is 20% less than that at diestrus, suggesting that rising levels of estrogen on proestrus leads to a reduction in the number of synapses. As estrogen levels decline, the number of synapses returns to baseline. Thus a disconnection and subsequent re-

connection of some neurons occurs within the arcuate nucleus during each ovarian cycle. These findings of synaptic plasticity may contradict our assumptions of the brain as a static tissue (the number of neurons does not change significantly in the adult arcuate nucleus), but recent studies suggest that regulation of synaptic number may occur in other parts of the central nervous system as well.[20]

Estrogen induces peroxidase activity within a class of neuroglial cells called astrocytes

Astrocytes within the arcuate nucleus also change dramatically after estrogen treatment—they develop large, electron-dense inclusions.[1-3] Originally called "gliosomes" they bear a striking morphologic resemblance to organelles called peroxisomes.[21] Peroxisomes use molecular oxygen and hydrogen peroxide to carry out oxidative reactions.[21] Like peroxisomes, gliosomes contain peroxidase activity.[22, 23] To determine whether gliosomes are peroxisomes, we are studying whether gliosomes contain other oxidative enzymes found in peroxisomes.

Peroxidase activity within the arcuate nucleus is sensitive to estrogen because estrogen treatment increases,[22, 23] and oophorectomy decreases[23] peroxidase within the arcuate nucleus. Arcuate nucleus neuroglial peroxidase behaves like peroxidases located in other estrogen-responsive tissues such as the breast, uterus, cervix, and vagina.[24, 25] The induction of arcuate nucleus peroxidase by estrogen is so robust and consistent that we[23] and others[24, 25] have used it as a marker of a tissue's estrogen responsiveness.

Recently we found that estrogen-sensitive peroxidase is not confined to the arcuate nucleus. When we surveyed serial sections through the entire brains of two rats for the presence of peroxidase activity with the 3,3′-diaminobenzidine reaction, we found that after the arcuate nucleus, the highest concentration of peroxidase activity resided in the periventricular nucleus. A number of other nuclei involved in the regulation of gonadotropin release such as the suprachiasmatic nucleus, medial preoptic area, and median eminence had minimal peroxidase activity.[23] When we compared peroxidase activity within the periventricular nucleus and arcuate nucleus of estrogen-treated, cycling, and oophorectomized rats, we found peroxidase was estrogen-sensitive in both of these nuclei. On the other hand, peroxidase activity within the posterior cingulate cortex, an area lacking estrogen receptors, was not estrogen-sensitive. It is of interest that the distribution of estrogen-inducible neuroglial peroxidase in the arcuate nucleus and periventricular nucleus closely overlaps that of estrogen receptor-positive catecholaminergic neurons that have been implicated in neuroendocrine regulation,[26] raising the possibility of some interaction between these peroxidase-rich neuroglia and estrogen-receptor positive catecholaminergic neurons. Furthermore, because estrogen induces peroxidase activity in the periventricular nucleus, it would be of interest to determine whether it induces synaptic remodeling in the periventricular nucleus as well.

Whereas peroxidases may protect cells from the harmful effects of free radicals by breaking down hydrogen peroxide, they can also contribute to oxidative stress by catalyzing the oxidation of some molecules including estrogen and catecholamines

We do not completely understand the function of estrogen-inducible neuroglial peroxidase and its relationship to estrogen-induced synaptic plasticity, but we can make some generalizations on the basis of studies carried out in other systems. Peroxidases are present to varying degrees in every cell, where they protect the cells from the harmful effects of hydrogen peroxide and associated free radicals produced during oxidative reactions.[21] In addition, peroxidase can generate free radical intermediates by catalyzing the oxidative metabolism of some molecules including estrogen[27, 28] and catecholamines.[29] Thus under different conditions peroxidase can inhibit or promote the formation of free radicals.

A free radical is a molecule with an unpaired electron in its outer orbit, making it highly unstable and quite reactive.[30] Free radicals form from oxygen during normal aerobic cellular metabolism, as well as during the oxidative metabolism of a number of cellular constituents such as estrogen and catecholamines.

Although free radicals generated during oxidative reactions threaten to damage cellular constituents, cells use a number of defensive strategies to contain the toxic effects of free radicals. First, a variety of enzymes including various peroxidases and superoxide dismutase catalyze the breakdown of free radicals and hydrogen peroxide.[30] In some species intracellular oxidative stress itself induces the synthesis of peroxidases and antioxidant enzymes. This effect is mediated by a protein whose oxidized but not reduced form activates transcription of peroxidase and antioxidant genes.[38] Second, peroxidases,[39] superoxide dismutase,[40] and many oxidizing enzymes[39, 40] have signal sequences that target them to peroxisomes or mitochondria. Within these specialized compartments, enzymes that generate peroxide and free radicals remain in close proximity to enzymes that break down these toxic species. Finally, a number of antioxidants including vitamins E and C and carotenes scavenge oxygen free radicals in the cell's hydrophobic and hydrophilic domains.[31]

Whereas most cells contain the toxic effects of free radicals with these defensive strategies, other cells har-

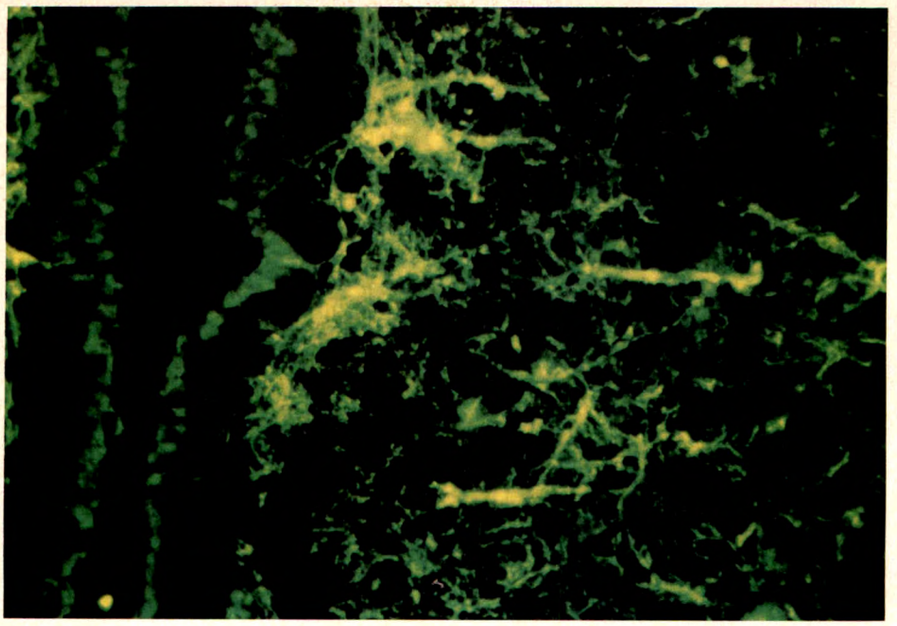

Fig. 1. This epifluorescence micrograph shows binding of fluorescein-conjugated estradiol to stellate cells within the arcuate nucleus of the rat hypothalamus. Cells stained with the fluorescein-conjugated estradiol appear green-yellow in these 10 μm-thick cryostat sections. The third ventricle can be seen on the left-hand side of the photomicrograph. The distribution of fluorescein-conjugated estradiol binding overlaps that of astrocytes that contain estrogen-inducible peroxidase.

ness these toxic molecules to serve specialized functions (e.g., leukocytes and macrophages use free radicals during the immune response,[41] and the tissue remodeling in the postfertilization envelope in the oocyte of some species[42] and the regressing corpus luteum[32, 33] involve free radicals). Free radicals also may bring about pathophysiologic damage to the central nervous system such as in ischemic reperfusion injury[42] and Parkinson's disease.[43]

In addition to breaking down hydrogen peroxide, peroxidases can catalyze a number of reactions that produce free radicals as intermediates. These include the metabolism of estrogen through the catechol estrogen pathways, which produce reactive quinones and semiquinones,[36, 37] and the oxidation of catecholamines by monoamine oxidase.[44]

Estrogen-induced peroxidase and free radical production provide a hypothetical mechanism to explain the molecular basis of estrogen-induced synaptic plasticity

We do not understand how estrogen, peroxidase, and free radicals relate to synaptic remodeling within the arcuate nucleus. However, the information from the rapidly growing field or free radical biology summarized in this article allows us to construct hypotheses that can be tested experimentally. One possible hypothesis is that estrogen induces synaptic remodeling independent of any effects on peroxidase or free radicals, and that the neuroglial activation observed within the arcuate nucleus represents only a reaction to tissue damage. Alternatively, estrogen could directly induce synaptic damage in the arcuate nucleus through its reactive oxidative metabolites. In this hypothesis, oxidative metabolism of estrogen catalyzed by peroxidase initiates a vicious cycle in which free radical intermediates that arise during the oxidative metabolism of estrogen induce further synthesis of peroxidase, resulting in further production of free radical intermediates. In this way estrogen provided by physiologic surges or pharmacologic administration could produce free radicals, induce peroxidase, and lead to synaptic damage.

Although estrogen induces peroxidase in neuroglia, conventional assays have never demonstrated estrogen receptors in these cells

Although estrogen induces peroxidase activity in neuroglial cells within the arcuate nucleus and periventricular nucleus, neuroglial cells themselves do not contain estrogen receptors as determined by autoradiography[45] or in situ hybridization with an oligonucleotide probe for the estrogen receptor.[46] A number of mechanisms could account for estrogen inducibility of peroxidase in the absence of estrogen receptor. First, even in the absence of estrogen receptors, oxidative

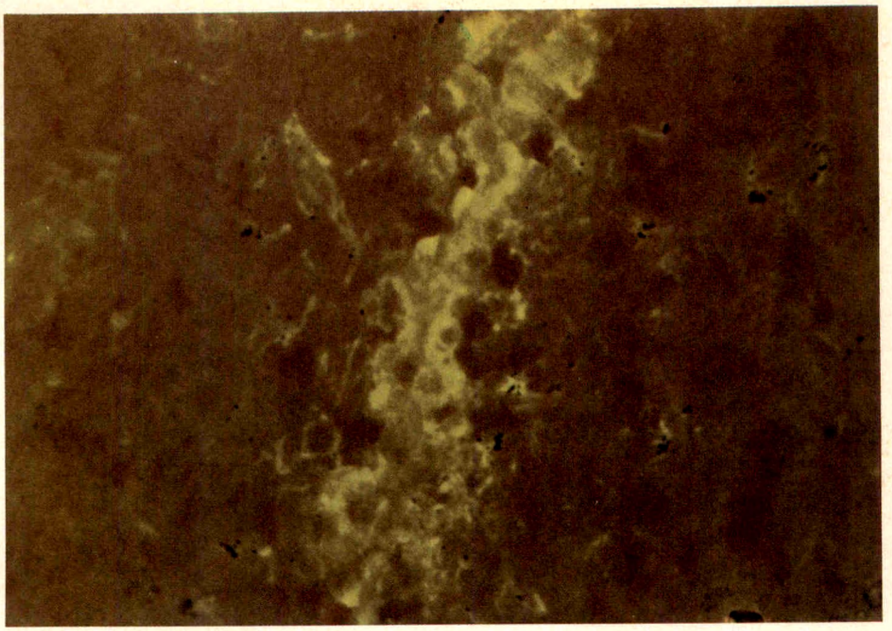

Fig. 2. This epifluorescence micrograph shows that many cells within the arcuate nucleus both contain peroxidase as measured by 3,3′-diaminobenzidine *(black granules)* and bind fluorescein-conjugated estradiol *(green-yellow)*.

metabolism of estrogen might directly induce peroxidase activity in neuroglial cells by increasing intracellular oxidative stress.[38] Alternatively, estrogen could bind to estrogen receptors in neurons and induce the secretion of some factor that induces peroxidase in surrounding astrocytes by paracrine action. One candidate for mediating such a neuron-neuroglial interaction is nerve growth factor, which induces peroxidase activity in PC-12 cells in culture.[47] A third possibility is that estrogen might act directly on neuroglial cells in some novel estrogen receptor–independent manner. Tsibris et al.[48] recently described a family of proteins with structures that share homology with the estrogen-binding domain of the estrogen receptor. Furthermore, he showed that estrogen can influence the enzymatic activity of at least one of these proteins in vitro.[48] This and other data[49] suggest that estrogen does not always require the presence of its classical receptor in a cell to influence that cell's function.

Peroxidase-rich neuroglial cells in the arcuate nucleus and periventricular nucleus of the hypothalamus bind fluorescein-conjugated 17 β-estradiol

Although neuroglial cells do not themselves contain nuclear estrogen receptors, they do bind estrogen as measured by an in vitro fluorescein-conjugated 17 β-estradiol (estradiol-bovine serum albumin-fluorescein isothiocyanate) histochemical technique,[50] which depends on permeabilitization of cells with freezing or detergents. This material reliably identifies breast cancer cells that are also receptor-positive, as determined by immunohistochemistry with a monoclonal antibody for the estrogen-receptor, and it predicts the efficacy of sex steroid manipulation therapy on breast cancer.[51] However, because it identifies nonnuclear binding,[50, 51] its relationship to the estrogen receptor is unclear.

Because a preliminary communication had suggested binding of this reagent to astrocytes,[52] and because we had found estrogen-inducible peroxidase activity in neuroglial cells that lacked classical estrogen receptors as measured by conventional methods, we used the in vitro fluorescein-conjugated estradiol histochemical assay to look for estrogen binding in cryostat sections of the female rat hypothalamus. We found almost all the fluorescein-conjugated estradiol confined to cells with the morphology of astrocytes (Fig. 1). Staining was especially prominent within the arcuate nucleus and periventricular nucleus, but was clearly different from the peroxidase (3,3′-diaminobenzidine reaction), which was also present. As reported previously in breast and uterus,[50, 51, 53] the probe did not label nuclei, but instead was confined to extranuclear sites in a distribution consistent with either cell cytoplasm or membrane.

Because labeled cells had the same morphology as astrocytes and appeared most numerous within the arcuate nucleus and periventricular nucleus in the same distribution as peroxidase-rich astrocytes, we looked for the presence of peroxidase activity and fluorescein-conjugated estradiol in the same cells. First we cut 10

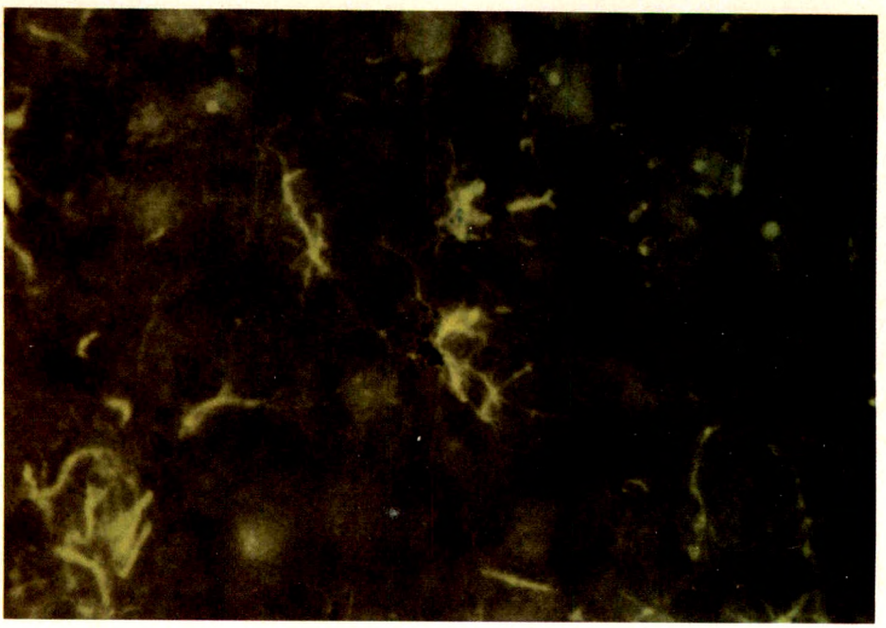

Fig. 3. Although many stellate-shaped cells in the arcuate nucleus both contain peroxidase and bind fluorescein-conjugated estradiol, the two labels appear in different compartments of the cell. Peroxidase, as indicated by the presence of 3,3′-diaminobenzidine granules, appears as distinct, dark granules, whereas fluorescein-conjugated estradiol binds widely throughout the cell. Thus fluorescein-conjugated estradiol appears to bind to neither nuclear receptors nor to peroxidase, but rather to some constituent of either cytoplasm or membrane.

μm-thick cryostat sections from the hypothalamus of estrogen-treated female rats. Then we stained these sections with the fluorescein-conjugated estradiol reagent. After fixing the sections in paraformaldehyde, we stained the sections for peroxidase activity using the 3,3′-diaminobenzidine reaction. We found many cells with the morphology of astrocytes that contained both 3,3′-diaminobenzidine granules and fluorescein-conjugated estradiol, and the distribution of these cells again overlapped that of peroxidase-rich neuroglia (Fig. 2). Although some cells appeared to contain either peroxidase activity or fluorescein-conjugated estradiol alone, inspection of the remainder of these cells in other sections frequently revealed the presence of both labels.

Although peroxidase and fluorescein-conjugated estradiol frequently appeared in the same cells, they always occupied different compartments within the cell (Fig. 3). 3,3′-Diaminobenzidine appeared as small, discrete cytoplasmic granules, whereas the fluorescein-conjugated estradiol labeling appeared homogeneous, suggesting that either it binds throughout the entire cytoplasm or that it labels some membrane component. Given the separate intracellular locations of peroxidase and fluorescein-conjugated estradiol, the fluorescein-conjugated estradiol clearly must not bind to peroxidase itself. Further studies will need to characterize and identify the fluorescein-conjugated estradiol-binding substance(s). In particular, it will be interesting to learn whether the estrogen-binding substance shares homology with the nuclear estrogen receptor or to estramustine binding protein,[54] another substance that binds a congener of estradiol and predicts response of some tumor cells to hormonal therapy. In the meantime, the reagent provides a fluorescent probe that should prove useful to identify these astrocytes for future morphologic studies.

Comment

In summary, estrogen induces synaptic plasticity and neuroglial peroxidase activity within the arcuate nucleus and periventricular nucleus of the rat hypothalamus. The finding of estrogen-induced peroxidase activity outside of the arcuate nucleus suggests the need for further studies of estrogen-induced synaptic plasticity in other nuclei. Estrogen-induced peroxidase activity could cause or result from synaptic plasticity, although recent studies that show that peroxidase activity and associated free radicals cause tissue damage and remodeling in a number of physiologic and pathologic situations support the former hypothesis. Furthermore, although estrogen induces peroxidase activity in neuroglial cells, neuroglia have never been found to bind estrogen by autoradiography or to contain the message for estrogen receptor by in situ hybridization.

We have identified binding of fluorescein-conjugated estradiol within these peroxidase-rich, but estrogen receptor–deficient neuroglial cells. Because the molecular basis of this binding remains controversial, future studies will need to further characterize and identify the substance that binds fluorescein-conjugated estradiol in neuroglia. These results raise questions about the role of peroxidase-rich neuroglia in the metabolism of estrogen and provide a fluorescent probe to identify them for future morphologic studies.

We are indebted to Dr. Alan Pooley of the Morphometrics Laboratory of Yale University for making available his image analysis system.

The role of the placenta in nutrition of the human fetus

Henning Schneider, MD
Berne, Switzerland

Bidirectional transport across the placenta provides substrates required for fetal nutrition and prevents accumulation of metabolites in the fetal compartment. Transmission of compounds across the placental barrier occurs by diffusion and carrier-mediated transport. The technique of dual in vitro perfusion of an isolated cotyledon has provided important data for the human placenta. The high degree of permeability for hydrophilic molecules was recently confirmed by in vivo measurements that allow estimates of flux across the human placenta for a number of compounds. The bidirectional nature in transplacental exchange requires asymmetry in flux from the maternal to the fetal side or vice versa, which can be assured by a concentration gradient or an active transport system. There is increasing evidence that placental metabolism with active modification of the composition of nutrients released to the fetus in addition to transport plays an important role. (AM J OBSTET GYNECOL 1991;164:967-73.)

Key words: Human placenta, bidirectional transport, in vitro perfusion, permeability

The human fetus together with the placenta, its supply organ, for a long time have been quite inaccessible to the investigator. Concerns for both fetal and maternal safety and ethical considerations placed severe restrictions on invasive research in human pregnancy. The bulk of information on fetal and placental physiology was obtained in animal experiments.

New technologies such as real-time ultrasonography together with Doppler ultrasonographic techniques have given us a direct view into the inside of the fetal world and provided us with new information on fetal and placental growth and blood flow in the major vessels. Blood sampling in the human fetus can be performed under almost undisturbed steady-state conditions at various stages of gestation, which seemed impossible only a few years ago. These new tools of research provide additional information, rapidly expanding the knowledge in particular on the human fetus and the human placenta.

It is obvious that the placenta plays a central role in fetal nutrition, and there is no survival of the fetus in utero without support by the placenta. Whereas the association of placental transport function and fetal nutrition is self-evident, other functional aspects, such as placental hormone synthesis and various metabolic activities, are also closely linked to the supply of nutrients to the fetus. Placental proteohormones secreted into the maternal bloodstream act as signals sent from the conceptus to the mother to induce important changes in the maternal cardiovascular system and in basic metabolism, which are needed to guarantee substrate flow through the placenta. Energy metabolism is not only needed to support the synthetic process, but also to maintain active transport across the barrier that separates maternal and fetal blood. Furthermore, there is increasing evidence that the placenta does not restrict itself to the simple transmission of the mixture of substrates that is presented by the maternal bloodstream, but there is continuous modification of the composition of nutrients through the metabolic activity within the placenta. This seems especially relevant to the supply of amino acids because essential amino acids of the branched chain structure, such as leucine, are to some extent converted and released into the fetal bloodstream as nonessential neutral straight chain amino acids such as alanine and glycine.[1,2]

Because placental transport function is affected by several factors, it should be discussed as an integral part of the maternal and fetal organism (Table I). Because of its easy accessibility, isolated human placental tissue was widely used to overcome some of the restrictions placed on research in human pregnancy. Any type of experiment performed with isolated placental tissue creates an artificial situation and can only provide part of the answer. Several techniques have been described, ranging from membrane vesicles with the use of only fractions of cellular material, villous preparations and slices to dual perfusion of either the whole organ or a single cotyledon. Important contributions were made by these techniques. Perfusion, which as an integrated system retains a good deal of the complexity of the intact organ, seemed particularly promising. Among other attractions it is the simplicity of the system, al-

lowing control of experimental variables, that leads to answers that are difficult to obtain in the complex in vivo set up. In this article, after a brief description of the perfusion technique, the validity of the approach will be discussed and some examples of the type of information on human placental transport derived from in vitro perfusion experiments will be presented. Some of these data are more relevant since new information on human placental transport obtained in vivo is available for direct comparison.

In vitro perfusion of human placental tissue

Technique. The technique for dual-perfusion of an isolated cotyledon was developed over 25 years ago and was repeatedly described in detail.[3, 4] Placentas are obtained immediately post partum. After selection of a suitable cotyledon, the supplying vessels are identified on the chorionic plate and cannulated for perfusion of the fetal vascular system of that particular cotyledon. The intervillous space is separately perfused via blunt cannula penetrating the decidual plate and the two perfusion circuits are maintained, one for the maternal compartment corresponding to the intervillous space and one for the fetal vessels inside the villi. The preparation is fixed in a temperature-controlled perfusion chamber and various parameters such as pressure, flow rates, temperature, pH, and gas partial pressures are monitored throughout the experiment.

Validity of in vitro perfusion. There was a great deal of questioning as to the validity of the data when they were first presented. Apart from unphysiologic conditions of any in vitro set up, the significant time lag between interruption of blood flow and initiation of in vitro perfusion was of serious concern. Over the years several investigators accumulated substantial evidence on the morphologic and functional integrity of the perfused tissue as shown by the continuation of hormone synthesis, active carrier-mediated transport, and the maintenance of the ultrastructure.[5-10]

The placenta, similar to early embryonic and other poorly differentiated tissues, has a higher degree of resistance to ischemia than mature tissues of similar metabolic activity as shown by the preservation of tissue adenosinetriphosphate after ischemia.[11] The significance of this general concept for in vitro placental perfusion has been shown by an on-line assessment of synthesis of energy-rich phosphates under conditions of various degrees of hypoxia including ischemia with magnetic resonance spectroscopy. After the start of in vitro perfusion, an increase in tissue adenosinetriphosphate with a simultaneous fall in inorganic phosphate could be shown and adenosinetriphosphate levels were maintained for up to 10 hours of perfusion. After total interruption of both perfusion circuits for 2 to 4 hours a complete recovery of adenosinetriphosphate generation could be shown with resumption of perfusion.[12]

Permeability to hydrophilic molecules in vitro

Passive diffusion across the placenta is an important mechanism for substrate exchange. Diffusional flux in the direction from the mother to the fetus contributes to fetal nutrient supply, whereas flux in the reverse direction allows for clearance of the fetal compartment from metabolites and other compounds. Limitation to diffusion is given by the resistance within the tissue layers interposed between fetal and maternal blood, which is significant for hydrophilic molecules. This is in contrast to lipid-soluble substances that show a much higher degree of permeability, with uterine and umbilical blood flows being the limiting factors for transplacental flux rates.[13] In the human placenta there are two layers that contribute to diffusional resistance, the trophoblast that covers the villi and the endothelium that lines the fetal capillaries inside the villi. Hydrophilic molecules have to find their way through water-filled channels that extend through the syncytiotrophoblast and communicate with intercellular channels in the endothelial layer.[14]

Large differences among species have been shown for placental permeability to hydrophilic molecules that must be explained by differences in the size of the water-filled channels. In the sheep the barrier is particularly tight with no diffusional flux for hydrophilic substances with a molecular weight > 400 daltons.[15] In contrast, the guinea pig placenta is much more permeable, allowing diffusion even for inulin with a molecular weight of >5000 daltons.[16] For smaller molecules such as mannitol the permeability of the guinea pig placenta is even 30 times higher. Whereas similarity in structure would suggest that the human placenta has a similar degree of permeability for hydrophilic molecules, some controversy remains.[17]

Evidence of the permeability of the human placenta comes from in vitro perfusion experiments and lately also from in vivo determinations performed during cesarean section. With the in vitro approach a wide range of different molecules that varied in size between 60 and 5000 daltons were studied. Labeled test compounds were added to the perfusion fluid circulating through the maternal compartment. By measuring the

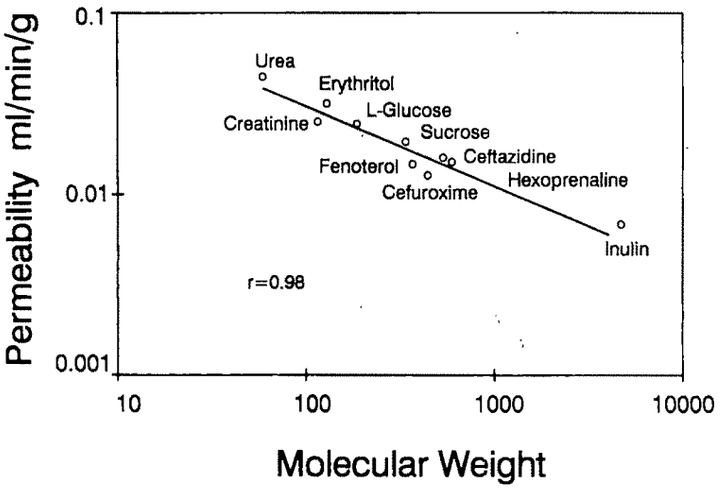

Fig. 1. Correlation between placental permeability and molecular weight for several hydrophilic compounds as determined by in vitro perfusion of an isolated human placental cotyledon. Data points for some compounds were taken from Schneider H, Sodha RJ, Prögler M, Young MPA. Permeability of the human placenta for hydrophilic substances studied in the isolated dually in vitro perfused lobe. Contrib Gynecol Obstet 1985;13:98-103.

flow rate in the fetal compartment together with the concentration of the test compound in fetal venous samples, the flux per minute and gram placental tissue can be calculated, from which the permeability is derived as the ratio of the flux over the gradient. Details of the experimental design have been described.[18] There is a close correlation between permeability and molecular weight over the studied range, indicating that free diffusion in water is the determining factor and that the water-filled channels are wide enough to allow unlimited passage for all hydrophilic molecules up to 5000 daltons (Fig. 1).

These data on the permeability of the human placenta for lipid insoluble solutes could be of great interest. Most electrolytes, urea, many drugs and peptides belong in this group. Over a wide range of different molecular sizes there is no steric hindrance within the human placental barrier, and diffusion is inversely proportional to molecular size. A good part of endogenous and exogenous hydrophilic compounds, which are of general interest in human pregnancy, fit in this range, and from the plot shown in Fig. 1 a permeability value can be taken for any substance. For clinical purposes and discussions in physiology, the flux or the amount of substance getting across the fetus is of more relevance than the permeability and this can be derived from the permeability, provided the transplacental gradient is known. With more and more information on fetal blood levels coming from samples obtained by cordocentesis, estimates on transplacental gradients can be performed and flux can be calculated as a product of permeability times transplacental gradient. A direct comparison of the flux values with figures on fetal requirements or fetal production will be of interest in particular for endogenous compounds and will indicate whether diffusional transport is adequate for supply or clearance or whether active transport or placental metabolism are involved as additional mechanisms.

Permeability to hydrophilic molecules in vivo

A principal question is to what extent does the experimental situation of in vitro experiments change the permeability characteristics of the barrier? Experiments in the guinea pig have shown that in situ perfusion yields higher figures on permeability than those in the intact animal and the discrepancy seems to be larger with increase in molecular size.[19] Recent data on human placental permeability determined at the time of cesarean section allow comparison between in vitro and in vivo results.[20-22] The two groups performed permeability studies of the human placenta in vivo using a similar approach that consisted of infusion of test molecules into women scheduled for elective cesarean section starting about 1 hour before surgery. Samples were taken from the anticubicle vein at the opposite arm at 20-minute intervals, whereas cord blood and amniotic fluid were obtained at the moment of delivery. The amount transferred to the fetus was determined either by collection of all the urine excreted by the newborn up to 50 to 60 hours after delivery or by use of the concentration in cord blood and a factor for the volume of distribution in fetal tissues. The mean transplacental gradient that is also needed to calculate per-

meability was taken from the area under the concentration curve derived from maternal samples and the cord blood sample. Because of the limited number of data points in particular for the fetal concentration curve, this can only lead to an estimate of the transplacental gradient.

Permeability values obtained by this direct in vivo measurement for mannitol and inulin together with the values obtained in vitro are shown in Table II. Whereas the in vivo values found for mannitol and inulin permeability by a group from London are smaller than the in vitro results, there is a fairly good agreement between in vitro and in vivo data as reported by a group from Portland.[21, 22] Possible explanations for the difference in results in the two in vivo studies have been discussed.[22] In view of the great individual variations shown in both in vivo studies, the data on permeability obtained by in vitro perfusion and in vivo measurements are not too different and can be used to give estimates of human placental permeability of any hydrophilic molecule within the described range. Both approaches—in vivo and in vitro—show a much higher permeability than what has been described for the four-layered sheep placenta. The in vivo permeability for mannitol, a molecule of the same size as glucose, is close to 60 times higher in the human placenta than in the sheep.[15]

It should be stressed at this point that the discussion of passive diffusion has been restricted to hydrophilic molecules and other factors such as partial lipid solubility, protein binding or carrier-mediated transport will lead to completely different rates of flux.

Asymmetry of flux

With consideration of the rather high degree of leakiness of the hemochorial placenta even for hydrophilic molecules, there is more or less free exchange of many compounds between maternal and fetal blood. Net flux of nutrients, electrolytes, vitamins, and other compounds from the mother to the fetus is needed to secure a constant supply for fetal energy metabolism as well as tissue growth and differentiation. Clearance of metabolites and end products, on the other hand, require net movement from the fetus to the mother. Directional flux with asymmetry in flux rates is a basic principal of transplacental substrate exchange. This asymmetry may be a result of a downhill gradient with net movement from the side of higher to lower concentration, or preferential transport may be provided by an active transport system independent of differences in concentration. The asymmetry of flux by carrier-mediated transport has also been studied in the in vitro perfused placenta.[8, 23]

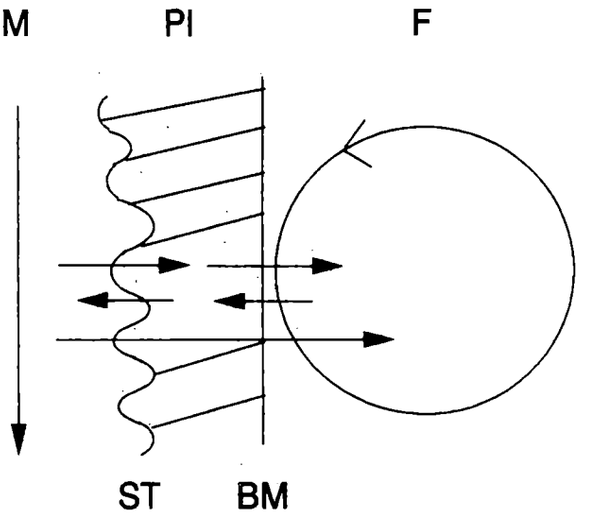

Fig. 4. Asymmetry in uptake and efflux at the maternal and fetal surface leading to asymmetry in transplacental flux. *M, F,* maternal, fetal perfusion circuit; *PI,* placental barrier; *ST,* syncytiotrophoblast; *BM,* basal membrane.

For this type of study a special experimental design with one perfusion circuit run as an open system and the other side recirculated has been applied (Fig. 2). The test compound under investigation is added to the perfusate on the open side, providing a constant level with no test substance present in the recirculating compartment. The change in concentration as a result of the appearance of test compound in the recirculating compartment allows calculation of the rate of flux. With the possibility of changing open and closed sides in the same or different experiments, the net flux in the two directions may be compared. As an example, the transfer rates of radioactively labeled α-aminoisobutyric acid is shown in Fig. 3. It is compared with two passively diffusing reference compounds: antipyrine, a small liquid-soluble molecule with rapid diffusion, and L-glucose. Both antipyrin and L-glucose show identical transfer when measured in the two directions, therefore only one concentration curve in the recirculating compartment is shown. The difference in transfer rate between antipyrine and L-glucose is a result of the difference in solubility, with antipyrine being highly lipid soluble whereas L-glucose is a purely hydrophilic molecule. α-Aminoisobutyric acid shows a clear asymmetry with a higher flux from the mother to the fetus. It is interesting that the back flux from the fetal to the maternal side is even lower than that of L-glucose, although α-aminoisobutyric acid is a smaller molecule, suggesting that there is less back flux for the amino acid as would be expected by passive diffusion. Ex-

traction of perfused tissue at the end of the experiment showed accumulation of the amino acid in the tissue with no significant difference in the two types of experiments. Similar differences in flux could be shown for representatives of other amino acid transport systems such as leucine or lysine.[8]

Comparison among three different amino acids showed a significantly higher transfer rate for leucine than for α-aminosobutyric acid or lysine, confirming results from animal experiments that showed that transfer of neutral branched chain amino acids is faster than that of neutral straight chains such as alanine or glycine as well as basics such as lysine.[24, 25]

Whereas the asymmetry in flux across the placenta seems to be an important mechanism in transport and has been shown for water-soluble vitamins such as riboflavin,[23] the mechanism that explains the difference in flux in the two directions is not completely understood. The kinetic equilibria at the maternal and fetal surface of the placenta are of a complex nature and are involved not only in the development of gradients between the bloodstream and the tissue but also in the transplacental gradient expressed as the difference between maternal and fetal concentration (Fig. 4). A rapid uptake of the compound at the maternal surface with the microvillous covering of the syncytiotrophoblast seems to be of primary importance. At this interface uptake greatly exceeds substrate release and a cotransport of amino acids with sodium dependent on sodium/potassium–adenosinetriphosphatase activity has been shown for human placental membrane vesicles prepared from the microvillous surface.[26, 27] There is some evidence for uptake of amino acids from the fetal side as well as could be shown in the isolated guinea pig placenta.[28] The asymmetry of uptake and efflux at both interfaces between maternal blood and trophoblast and fetal blood and capillary endothelium are contributing to transplacental transport. Whereas uptake and efflux on both sides are involved in the transplacental flux of neutral amino acids, the uptake of the acidic amino acid glutamic acid, which was shown from maternal and fetal blood, predominantly serves placental metabolism because there is no net flux across the placenta in either direction.[29, 30]

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1991 issues from the Publisher, at a cost of $61.00 for domestic, $88.27 for Canadian, and $84.00 for international for Vol. 164 (January-June) and Vol. 165 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Pulmonary injury associated with antepartum pyelonephritis: Can patients at risk be identified?

Craig V. Towers, MD, Carol M. Kaminskas, MD, Thomas J. Garite, MD, Michael P. Nageotte, MD, and Wendy Dorchester, MPH
Orange and Long Beach, California

The development of pulmonary injury in cases of antepartum pyelonephritis is rare but serious. To date, factors that might identify patients at risk have not been determined. We compared 11 patients with pyelonephritis and pulmonary injury with 119 patients with pyelonephritis only. Pulmonary injury was more likely to occur in the more severe cases; however, the presence of a maternal heart rate >110 beats/min and a fever to 103° F 12 to 24 hours before the occurrence of respiratory symptoms in a gestation >20 weeks was highly predictive of pulmonary injury. The most significant predictive factors associated with pulmonary injury were elements of treatment such as fluid overload, use of tocolytic agents, and, to a lesser extent, choice of antibiotic. Therefore, if tocolytic agents are considered at all in the management of acute pyelonephritis in pregnancy, they should be used only in patients with documented cervical change. In addition, urinary output should be monitored very closely. These data also may suggest a cause of the pulmonary edema that is occasionally seen in the management of premature labor with the use of tocolytic agents and fluids in the presence of a possible occult infection. (Am J Obstet Gynecol 1991;164:974-80.)

Key words: Pyelonephritis in pregnancy, pulmonary insufficiency in pregnancy, tocolytic complications

Adult respiratory distress syndrome is a well-known risk that is associated with sepsis[1] but occurs relatively rarely during pregnancy.

Pyelonephritis complicated by pulmonary injury was first reported in four patients in 1984 by Cunningham et al.[2] They postulated that the injury was endotoxin induced, which caused alveolar-capillary injury leading to respiratory injury. Two other individual cases were reported[3, 4] in patients with similar histories.

In 1987 Cunningham et al[5] reported on 15 antepartum patients, identified during a 7-year period, who had respiratory insufficiency with pyelonephritis. These patients were compared with 30 matched control subjects. A higher incidence of multisystem disorders, such as tachycardia, hemolysis, etc., was found in those patients in whom pulmonary injury ultimately developed. However, no clinical risk factors that could be used on admission to predict pulmonary injury were identified.

The purpose of this study was to review our experience with pyelonephritis to determine if any risk factors could be isolated to identify patients at risk for pulmonary injury.

Material and methods

All cases of antepartum pyelonephritis treated at the University of California Irvine Medical Center and Long Beach Memorial Womens Hospital from Jan. 1, 1985, to Dec. 31, 1988, were identified by medical record computer files. Pyelonephritis was defined as a positive urine culture with ≥100,000 cfu/ml of a single species of bacteria,[6] maternal fever ≥38° C (100.4° F), and flank pain with tenderness on examination. All three findings, in addition to a viable pregnancy, were necessary for inclusion of patients in the data analysis.

These cases were reviewed for historic, clinical, and treatment factors. Historic factors included gravidity, parity, gestational age, prenatal care, and a history of pyelonephritis. When clinical factors are evaluated, mean values are not very helpful in the identification of predictive parameters. Therefore a modified step analysis was used on each variable to determine cutoff points. Clinical factors included maximum maternal heart rate, maximum maternal respiratory rate, maximum temperature, days febrile (≥38° C) after admission, blood transfusion, presence of renal or ureteral stone, microorganisms cultured, and elevated serum creatinine level. Treatment factors included use of tocolytics, fluid management, and choice of antibiotic.

Pulmonary injury was characterized by dyspnea, tachypnea, documented hypoxemia with a need for

Table I. Risk of pulmonary injury with antepartum pyelonephritis with respect to historic factors

Factor	*Pyelonephritis without pulmonary injury*	*Pyelonephritis with pulmonary injury*	*p Value*
Mean gravidity	2.46 ± 1.63	1.73 ± 0.94	0.41
Mean parity	0.94 ± 1.19	0.55 ± 0.97	0.71
Prenatal care	31/119	4/11	0.59
Gestational age >20 wk	84/119	11/11	0.036
History of pyelonephritis	6/119	1/11	0.35

Table II. Clinical factors in determining the risk of pulmonary injury with antepartum pyelonephritis

Factor	*Pyelonephritis without pulmonary injury*	*Pyelonephritis with pulmonary injury*	*p Value*
Maternal heart rate* ≥ 110 beats/min	13/119	11/11	<0.00001
Respiratory rate >28 breaths/min	4/119	11/11	<0.00001
Fever ≥103° F (first 24 hr)	13/119	9/11	<0.00001
≥3 Febrile days in hospital	16/119	10/11	<0.00001
Transfusion needed	0/119	4/11	<0.00001

*Heart rate 12 to 24 hours before symptoms of respiratory insufficiency occurred.

supplemental oxygen, and an abnormal chest radiograph consistent with pulmonary edema or adult respiratory distress syndrome.

All collected information was placed in a computer data file. The χ^2 test with Yates' correction and Fisher's exact test were used in statistical analysis. A p value of ≤ 0.05 was considered significant. All tests were considered against a two-sided alternative hypothesis. Factors that were potentially predictive of patients who were destined to have pulmonary injury were further subjected to multivariate analysis.

Results

A total of 214 cases of pyelonephritis were identified. Eighty-four were excluded because the patients did not meet all four criteria for having antepartum pyelonephritis. No case of pulmonary injury was seen in these 84 excluded cases. Eleven cases of pulmonary injury (8.5%) that met all four criteria occurred in the remaining 130. This allowed for comparison of 11 cases of pyelonephritis and pulmonary injury with 119 cases of pyelonephritis without pulmonary injury. Pulmonary injury occurred within 36 to 72 hours of admission in all 11 cases.

Gravidity, parity, prenatal care before admission, and a history of pyelonephritis were not significantly correlated with pulmonary injury (Table I). However, pyelonephritis with pulmonary injury occurred significantly later in gestation with all cases occurring after 20 weeks' gestation.

Clinical factors were highly significant in correlating pyelonephritis with pulmonary injury (Table II). A maternal heart rate of ≥110 beats/min and a maximum temperature of ≥103° F (39.4° C) that occurred 12 to 24 hours before the onset of respiratory symptoms were very important. Maximum respiratory rate was evaluated at several intervals after admission and before pulmonary injury occurred. A respiratory rate of ≥28 beats/min, which was significant when compared with the maximum respiratory rate of the control group, occurred only when pulmonary injury was already apparent. No difference in the maximum respiratory rates of the two groups was found in the 12- to 24-hour period preceding the onset of pulmonary symptoms. Therefore the respiratory rate was not predictive of pulmonary injury.

The need for transfusion and the number of febrile days in the hospital also were significantly correlated with pulmonary injury. However, because all cases of pulmonary injury were apparent within 3 days of admission, the duration of fever also was not predictive. In addition, the four patients in whom transfusion was required received the units of blood after the diagnosis of pulmonary injury was made.

A serum creatinine level was obtained within 12 hours of admission in 89 of the patients. Only eight patients had a value of ≥1.0 mg/dl. In three of these patients pulmonary injury developed. The difference in the incidence of an elevated creatinine level was not significant ($p = 0.10$) between the two groups. *Esche-*

Table III. Antibiotics used as first line of treatment for first 48 hours after admission

Antibiotic used	*Cases with pulmonary injury*	*Cases without pulmonary injury*	*Total*
Ampicillin only	6	31	37
Cephalosporin only	5	72	77
Gentamicin only (or with ampicillin or cephalosporin)	0	14	14
Tobramycin	0	1	1
Trimethoprim-sulfamethoxazole	0	1	1
TOTAL	11	119	130

Table IV. Treatment factors and risk of pulmonary injury with antepartum pyelonephritis

Factor	*Pyelonephritis without pulmonary injury*	*Pyelonephritis with pulmonary injury*	*p Value*
Tocolytic use	10/119	7/11	<0.00001
Fluid balance*			
>2 L	32/119	7/11	0.017
>3 L	11/119	5/11	0.004
Ampicillin only as initial treatment	31/119	6/11	0.075

*Fluid balance calculated over the first 48 hours in cases without pulmonary injury and calculated until the occurrence of pulmonary injury in 11 affected cases.

richia coli was the microorganism cultured in 106 cases, 7 of which incurred pulmonary injury. Three of 14 cases in which *Klebsiella* was the infecting organism had pulmonary injury, and *Enterobacter* was identified in the final case of pulmonary injury. The microorganism identified was not significant ($p = 0.19$).

Table III shows the antibiotics used as the first line of treatment for 24 to 48 hours after admission. The choice of antibiotic was not significant, although there was a trend toward a higher risk of pulmonary injury with ampicillin only. Culture sensitivities indicated that only two of the 11 cases with pulmonary injury were resistant to the first-line antibiotic. Seventeen cases were culture resistant to the first-line antibiotic in the 119 cases without pulmonary injury; this finding was not significant ($p = 0.5$). Unfortunately, blood cultures were not routinely obtained, especially in the cases in which pulmonary injury did not develop. However, only one of the 11 cases with pulmonary injury had a positive blood culture; in the other 10 cases blood cultures were negative.

Table IV, which evaluates the treatment factors, reveals that fluid overload and the use of tocolytics were the most highly significant factors in the development of pulmonary injury. The fluid intake rates were similar in both groups; however, urinary output was less in the cases that ultimately developed pulmonary injury (Table V). Because pulmonary injury occurred 36 to 72 hours after admission, the mean fluid intake (via intravenous infusion, medications, and oral routes) was calculated on an hourly basis until pulmonary injury was detected. The mean hourly urinary output in these 11 cases was calculated in the same manner. In the 119 cases in which pulmonary injury did not develop, the mean hourly fluid intake and urinary output were calculated for the first 48 hours after admission. In addition, the difference in fluid intake and urinary output also was significant between the two groups.

In nine of the 17 cases in which tocolytic agents were used, magnesium sulfate was given (pulmonary injury occurred in four of these cases), and eight patients received terbutaline (three of these eight experienced pulmonary injury); this also was not significant ($p = 0.58$).

A multivariate analysis with the use of logistic regression was then performed on the data. Because the purpose of this article was to identify risk factors that predicted respiratory insufficiency, a model using only factors that were present before the pulmonary injury was created. This model included gravidity, parity, gestational age, prenatal care, a history of pyelonephritis, microorganisms cultured, maternal heart rate of ≥110 beats/min, temperature ≥103° F in the first 24 hours after admission, use of a tocolytic agent, choice of antibiotic, fluid overload >2 L, and fluid overload >3 L. The final model resulted in five significant factors with a multiple R^2 of 0.59. These factors, in order of significance, were a maternal heart rate of ≥110 beats/min that was present 12 to 24 hours before respiratory symptoms occurred, the use of a tocolytic agent, the use of ampicillin only as the first line of treatment, a temperature ≥103° F in the first 24 hours, and fluid overload >3 L.

In three patients with pulmonary injury placement of a Swan-Ganz catheter was necessary. All values were consistent with adult respiratory distress syndrome with normal to elevated cardiac output (8.0, 8.1, and 10.9 L/min) and normal to slightly elevated pulmonary capillary wedge pressures (11, 14, and 18 mm Hg). All

Table V. Comparison of mean fluid intake and urinary output between the two groups

*Fluid status**	*Pyelonephritis without pulmonary injury (N = 119)*	*Pyelonephritis with pulmonary injury (N = 11)*	*p Value*
Mean fluid intake (ml/hr)	173.2 ± 26.8	166.3 ± 34.3	0.44
Mean urinary output (ml/hr)	112.7 ± 24.4	82.5 ± 21.8	0.002
Difference in intake and output (ml/hr)	60.4 ± 20.4	83.8 ± 30.0	0.001

*Fluid status calculated during the first 48 hours in the cases without pulmonary injury, and fluid status calculated up to the occurrence of pulmonary injury in 11 affected cases.

patients with pulmonary injury had arterial blood gas analysis with P_{O_2} values of ≤65 mm Hg.

In this study there were 127 patients, three of whom had had pyelonephritis twice; this resulted in a total of 130 cases. Twenty-eight patients were lost to follow-up, and one patient underwent termination of her pregnancy. Six (6.1%) of the remaining 98 patients were delivered before 36 weeks of gestation; the remaining patients were delivered at term. Two of the preterm deliveries were in the pulmonary injury group; both had premature rupture of membranes. The risk of preterm delivery was not significant when compared between the two groups ($p = 0.13$). Finally, only two patients had renal stones, and one of these patients was in the pulmonary injury group.

Comment

The incidence of pulmonary injury in our patient population was unexpectedly high (8.5%) when compared with the data of Cunningham et al.[5] Several factors might explain this variation. The study by Cunningham et al. reported on 15 cases found during a 7-year period during which 750 cases of pyelonephritis occurred. The incidence of pulmonary injury was therefore 1 in 50 cases of antepartum pyelonephritis (2%). However, not all 750 cases were reviewed to ensure adherence to the strict criteria required for a diagnosis of pyelonephritis. Therefore some cases might have been excluded (as they were in our evaluation), which would result in a smaller denominator and an overall higher incidence of pulmonary injury. Indeed, the cases excluded from our study were those of less severe illness. In addition, Cunningham et al. compared the 15 cases with 30 matched controls and did not find fluid management to be a factor. Also, tocolytic agents were not used. In our study two cases of pulmonary injury did occur when tocolytics were not used and when fluid overload was not present. This would suggest a baseline risk of 1 in 65 cases (1.5%), which is consistent with the data from the study by Cunningham et al. However, if fluid management is not closely monitored and if tocolytics are used in such patients, the incidence of pulmonary injury can be markedly increased, as this study indicates. Therefore it is important for clinicians to realize that a relatively benign disorder can be transformed into a very severe illness from iatrogenic causes if close monitoring is not observed.

It was somewhat amazing to see the high fluid intake measured on an hourly rate (Table V) in the management of these cases. This high fluid intake was probably instituted on the premise that part of the treatment regimen for pyelonephritis is to "flush" the kidney. For the most part, this management was tolerated by the patients in this study. However, if urinary output does not stay in line with the intake rate, then the patient is at high risk for incurring pulmonary injury. Thus prudent management of fluid intake and output is essential.

All 17 previously published cases,[3-5] as well as the 11 cases in this study, were >20 weeks of gestation, except for one case, which was at 19 weeks. This suggests that the occurrence of pulmonary injury as a result of pyelonephritis is dependent on gestational age.

Our study does reveal that pulmonary injury is more likely to occur in the more severe cases of antepartum pyelonephritis as indicated by highly significant clinical factors. The study by Cunningham et al.[5] confirms this with respect to tachycardia, tachypnea, febrile state, hemolysis, etc. However, the presence of maternal renal insufficiency that was significant in Cunningham's article was not significant in this study when it was evaluated in the first 24 hours of admission as a potential predictor of pulmonary injury. The development of pulmonary injury with *E. coli* pyelonephritis was 6.6% (7/106) versus 21.4% (3/14) with *Klebsiella* pyelonephritis; this was not significant. However, this may not have reached statistical significance as the result of a β-error in our study population.

The use of ampicillin only as initial treatment was highly implicated as a risk factor in the development of pulmonary injury, although results of the study were not conclusive. Therefore an aminoglycoside might be added to the initial treatment plan, especially in the treatment of the more severe cases of antepartum pyelonephritis.

The pathophysiologic parameters of pulmonary injury in the majority of our cases were probably multifactorial. Sepsis can cause alveolar capillary injury, but

the degree of capillary injury may vary from mild to severe. The addition of excess fluid can result in increased pulmonary capillary wedge pressure and in decreased oncotic pressure, and the addition of tocolytics raises cardiac rate, which increases left atrial pressure, as well as pulmonary venous pressure. Thus, in cases of milder degrees of alveolar capillary injury that would not ordinarily result in pulmonary edema, the addition of β-sympathomimetics or magnesium sulfate and excess fluid could cause frank pulmonary edema. The cardiac output and pulmonary capillary wedge pressure in each of our three patients who underwent invasive hemodynamic monitoring support this suggested mechanism.

The clinical implications of the information presented in this study are relatively straightforward for patients with pyelonephritis, but the data also may increase our understanding of the mechanism for at least some cases of pulmonary edema that are associated with tocolytic therapy for premature labor. The majority of reports describing pulmonary edema in patients with premature labor involve the use of β-sympathomimetic agents; however, pulmonary edema has been reported with the use of magnesium sulfate as well. Most patients in whom pulmonary edema develops do not have underlying cardiac disease and, while they often are given excess fluids, fluid overload alone generally does not explain the severity of the response. Reports of these cases have not suggested a cardiogenic cause of the pulmonary edema.[6-8] Furthermore, experimental trials in animals have failed to reproduce pulmonary edema with fluid overload and the use of β-sympathomimetic agents without also inducing a capillary permeability defect.[9, 10] After having reviewed all the reported cases of pulmonary edema associated with premature labor and tocolytic therapy, Benedetti[11] suggested that the majority of the patients in whom this complication developed might also have an unrecognized septicemia in association with an occult infection, such as occult chorioamnionitis. Therefore he contended that the apparent pulmonary edema in those cases was secondary to pulmonary injury caused by undiagnosed sepsis. The information obtained from the patients in this study supports Benedetti's argument, because the risk of pulmonary injury was markedly increased if tocolytics were used and if the patients had fluid overload.

In summary, tocolytic agents should be used only to treat the contractions of those pregnant patients with pyelonephritis who have documented and significant cervical change. The perceived benefit of tocolytic therapy must be weighed against the significant risk of pulmonary injury. Futhermore, strict management of fluids should occur so that patients do not have fluid overload. The warning signs of high fever (≥103° F) and a maternal tachycardia (≥110 beats/min) during the first 24 hours of admission are highly significant risk factors and should be closely monitored, especially if the patient is >20 weeks of gestation.

Discussion

DR. STANLEY A. GALL, Louisville, Kentucky. The authors have reviewed the clinical course of patients who have been diagnosed with acute pyelonephritis without pulmonary injury and have compared them with a smaller group of patients with acute pyelonephritis pulmonary injury as manifested by adult respiratory distress syndrome. The main question asked of the study is whether patients at risk for adult respiratory distress syndrome can be identified by clinical factors.

The authors were careful to select patients that constituted a homogeneous group by requiring four findings to be present. These included a positive urine culture of a single species of bacteria, maternal fever of ≥38° C, and flank pain with tenderness on examination. Eighty-four of 214 patients (39%) with a diagnosis of acute pyelonephritis were excluded because they did not meet all four criteria. These were appropriate exclusions because no cases of adult respiratory distress syndrome occurred in the excluded group and the excluded group had milder disease. Thus 119 of 130 patients (91.5%) with acute pyelonephritis and without adult respiratory distress syndrome were compared

with 11 of 130 patients (8.5%) with acute pyelonephritis and in whom adult respiratory distress syndrome occurred. It is important to note that the definition of pulmonary injury required the presence of dyspnea and tachypnea, the need for supplemental oxygen, the presence of hypoxemia, and an abnormal chest radiograph consistent with adult respiratory distress syndrome or pulmonary edema.

The authors report that gravidity, parity, the presence of prenatal care before admission, and a history of pyelonephritis were not significantly related to adult respiratory distress syndrome; however, all patients with adult respiratory distress syndrome were >20 weeks of gestational age. The clinical factors found to be highly significant were a maternal heart rate ≥110 beats/min and a maximum temperature of ≥39.4° C that occurred 12 to 24 hours before the onset of respiratory symptoms. The iatrogenic factors that were highly significant for adult respiratory distress syndrome included tocolytic use and excess fluid balance of >2 and >3 L. There was a trend toward significance with ampicillin as the only therapy.

The use of tocolytic agents in 17 of 130 patients (13%) with acute pyelonephritis resulted in the antibiotic treatment of 7 of 11 patients (64%) with adult respiratory distress syndrome; 4 of 9 (44%) received magnesium sulfate and 3 of 8 (37.5%) received terbutaline. The authors state that intravenous infusion rates were similar in groups with and without adult respiratory distress syndrome but that urinary output was less in the group with adult respiratory distress syndrome.

It seems to follow that the patients in whom acute pyelonephritis developed were those with a maternal heart rate of ≥110 beats/min 12 to 24 hours before the respiratory symptoms and who were treated with a tocolytic agent, received ampicillin as first-line chemotherapeutic agent, had a temperature of ≥39.4° C in the first 24 hours after admission, and had fluid overload >3 L. Study data indicated that adult respiratory distress syndrome with acute pyelonephritis was identified in 7 of 130 patients (5.3%) when tocolytics were used and in 2 of 130 patients (3%) when tocolytics were not used. It is unclear what happened to the remaining 2 of 11 patients (18%) with adult respiratory distress syndrome, because four received magnesium sulfate, three received terbutaline, and two did not received a tocolytic agent. Therefore my first question concerns what the other two patients received.

My additional question addresses the use of criteria of a pulse of 110 beats/min and a temperature of 39.4° C. Were the total intravenous infusions on a daily basis different among the seven patients who received tocolytic agents and in whom adult respiratory distress syndrome developed as compared with those who did not receive tocolytic agents and in whom the syndrome did not develop?

It would be of additional value to us if the fluid balance studies were explained more completely. The authors report that the total intravenous fluid infusions were similar in the two groups of patients but that the urinary output was lower in the group with adult respiratory distress syndrome, even though cardiac output was increased and serum creatinine level was normal. Is there an explanation for this unusual observation?

The authors are to be commended for using strict clinical criteria and for carefully analyzing this important disease entity. Their conclusions that clinical and iatrogenic factors can predict patients who are at high risk for development of adult respiratory distress syndrome are justified. I feel that this is a significant advance in our understanding of the disease entity of adult respiratory distress syndrome as a complication of acute pyelonephritis of pregnancy.

Dr. Ronald S. Gibbs, Denver, Colorado. I have three questions. The first involves the 84 exclusions that represent approximately 39% of the patients. First of all, how many patients, if any, were excluded because of colony counts <100,000 CFU/ml (a usual standard) but who may have had colony counts >100 CFU/ml?

Stamm reported that 100 CFU/ml was actually a more sensitive measure than 100,000 CFU/ml in symptomatic individuals.

Second, are the risk factors still the same if all 84 exclusions are added back in?

Third, was the identification of particular organisms related to pulmonary injury? I think that the Dallas group had reported *Klebsiella* as an associated organism. It was not found in this study, but the numbers seem to indicate that >20% of the *Klebsiella* isolates were associated with pulmonary injury as compared with an association of only about 5% of the *E. coli* isolates.

Dr. Thomas H. Kirschbaum, Los Angeles, California. I would like to ask the authors to comment on the certainty with which they can make this diagnosis without measuring the pulmonary capillary wedge pressure. We find that pulmonary capillary wedge pressure is commonly elevated in patients in whom we suspect the diagnosis. These patients do get better as a result of diuresis, and they may have additional endothelial injury but we can't be certain.

Dr. David A. Eschenbach, Seattle, Washington. It's fairly apparent that, with respect to pathophysiologic characteristics, either lipopolysaccharide or other material from the organism is causing some effect on the lung. A couple of iatrogenic problems such as tocolytics and fluid overload, have been identified. Could ampicillin therapy be another iatrogenic problem, in the sense that about 25% or more of urinary isolates are somewhat resistant to ampicillin?

Is it possible to determine whether the patients in whom pulmonary injury developed were those who had isolates that were resistant to ampicillin, which suggests that an inability to effectively treat the infection was an additional factor?

Dr. Robert K. Creasy, Houston, Texas. There seemed to be some question about exactly which injury the patients really experienced. There are some similarities that can be drawn with pulmonary edema treated with tocolytics alone. For example, it's relatively rare to see a patient experience pulmonary edema within the first 24 hours of treatment with a tocolytic

agent. The patients in this study were, I believe, experiencing pulmonary edema within 36 to 72 hours after tocolytic treatment. This is the time span within which most cases of pulmonary edema associated with tocolytics occur.

I think it's also relatively well established now that fluid overload predisposes patients receiving tocolytic therapy to pulmonary edema, and indeed a number of the patients in this study had significant overload.

The next question is whether pulmonary edema leads to adult respiratory distress syndrome, which has been shown to occur with tocolytic treatment alone, or does the patient really just have adult respiratory distress syndrome?

Dr. Garite (Closing). I appreciate the comments from Dr. Gall and the discussion. In response to Dr. Gall's questions, I apologize that the information was somewhat unclear. Seven of the 11 patients in whom pulmonary injury developed had had tocolytic treatment with or without excess fluid. Two had excess fluid only, and two had neither risk factor. I meant to imply that two of the 11 patients had neither risk factor when I made that statement.

There are two answers to the questions about the necessity of cutoff points and the reasons that we selected cutoff points with clinical factors that are predictive of pulmonary injury, such as tachycardia or fever. First, we felt that the purpose of this study was to determine whether there were clinically predictive risk factors. Therefore choosing a cutoff seemed more appropriate than choosing averages that a clinician could use to ascertain a need for concern about the patient's condition. We did a form of stepwise analysis that examined cutoff points found only infrequently. If you review the table that examines clinical factors, you will note that all cutoff points chosen (for example, high fever or tachycardia) occurred in $<10\%$ of the total population.

Total intravenous fluids were indeed similar in patients who had pulmonary injury and in those who did not have pulmonary injury, at least up until the mean of 48 hours.

The observation about oliguria is very cogent, especially as it pertains to patients with normal or elevated cardiac output with accompanying normal creatinine levels. Let me clarify that point. We examined creatinine on admission for two reasons. First, we were looking at the predictive value of a clinical entity. Second, in $>95\%$ of all patients included in the study, a creatinine level was determined, so this was a useful parameter. However, only patients with pulmonary injury or another complication had a repeat creatinine measurement, so it wasn't fair to compare the subsequent test result.

Half of the patients with pulmonary injury had an elevation in creatinine level >1.0 after pulmonary injury. So, as Cunningham and others have mentioned, patients often have multisystem disease; possibly endotoxin damages the endothelium within the glomerulus, which results in oliguria.

I would also like to respond to Dr. Gibbs' question about the 84 patient exclusions. Approximately half of these exclusions were as a result of our having isolated multiple organisms in the urine or as a result of colony counts $\leq 10^5$ Cfu/ml. Many patients were excluded because of lost urine cultures that occurred predominantly at the public institution, and very few patients were excluded because of absence of other clinical factors.

The risk factors were not analyzed, so I cannot answer that question.

The interesting observation in Cunningham's study that concerned *Klebsiella* as a more predominant cause of pulmonary injury than *E. coli* was not found in our study. In Fisher's exact test or a χ^2 test analysis, I can't remember the numbers specifically but the p value demonstrated a slight but not significant trend. If there is a trend, it certainly would require larger numbers; I can't comment on that further.

Dr. Kirschbaum questioned the certainty of the diagnosis without pulmonary monitoring. Of course, this is a very important point. First, cardiac disease must be ruled out, and the level of fluid overload must be assessed. Fluid overload can be determined in part by clinical response, because patients with adult respiratory distress syndrome tend to have clearance at a slower rate than do patients with simple fluid overload. Fluid overload also can be determined in part by a chest radiograph, but there is certainly a debate over this.

Beyond that, I think it just makes clinical sense that pulmonary edema is unlikely to occur from minor degrees of fluid overload in the presence or absence of cardiac disease.

Dr. Eschenbach commented on the sensitivity of antibiotics in the treatment of pulmonary injury. He questioned whether the organisms created the pulmonary injury and, if so, if these organisms were insensitive to ampicillin. Some were. I don't have the exact numbers, but somewhere between a third and a half were insensitive. That's about what we would expect with the sensitivity of coliforms to ampicillin in our hospital. With that small number, it's hard to speculate more than we already have, but we did consider this, although we did not include the data in our manuscript.

Finally, Dr. Creasy commented on the similarities of treatment with tocolytics in patients with preterm labor who did not have pyelonephritis. Those similarities were extremely striking to us as well. The similarities in timing of the onset of the disease and the similarities in the pulmonary and cardiac monitoring data in patients who have had invasive monitoring are quite tremendous. I think that most patients require some additional insult beyond mild pulmonary capillary injury to cause them to have frank pulmonary edema.

In a review of seminars in pulmonary medicine in 1986, it was commented that probably 80% to 90% of cases of pulmonary injury or adult respiratory distress syndrome are not clinically apparent but are transient. Unless patients have some other injury, such as overwhelming sepsis, shock, or trauma, they don't manifest pulmonary injury, and this may indeed be the case with tocolytic treatment and fluid overload.

Randomized comparative trial of indomethacin and ritodrine for the long-term treatment of preterm labor

Richard E. Besinger, MD, Jennifer R. Niebyl, MD, William G. Keyes, MD, PhD, and Timothy R.B. Johnson, MD

Baltimore, Maryland

A randomized prospective trial was performed to compare the efficacy and safety of ritodrine and indomethacin in the long-term treatment of preterm labor. Forty patients with intact membranes in preterm labor at 23 to 34 weeks' gestation were randomized to receive either intravenous ritodrine or oral indomethacin as the first-line tocolytic agent. Successful intravenous ritodrine therapy was followed by oral terbutaline therapy, and indomethacin-treated patients continued to receive oral indomethacin. Treatment failures were defined as progressive preterm labor or patient intolerance, and these patients were treated with intravenous magnesium sulfate. Ritodrine and indomethacin were equally successful in delaying preterm birth as defined by interval to delivery, gestational age at delivery, delivery delayed >7 days, attainment of 35 weeks of gestation, percentage of patients who required magnesium sulfate therapy, percentage of patients who were readmitted with premature rupture of membranes, absence of recurrent preterm labor, and infant birth weight. More than 80% of mothers who received ritodrine voiced complaints of β-sympathomimetic side effects, and one patient discontinued treatment as the result of intolerance. There were minimal patient complaints with indomethacin use. No statistically significant differences were noted in neonatal outcome as defined by Apgar scores, umbilical cord pH, intensive care days, ventilator days, or neonatal deaths. However, three cases of primary pulmonary hypertension were observed in the indomethacin group. We had not previously observed this problem with short-term (24 to 48 hours) indomethacin therapy. (Am J Obstet Gynecol 1991;164:981-8.)

Key words: Indomethacin, ritodrine, tocolysis

Inhibition of preterm labor remains a major therapeutic dilemma in modern-day obstetrics. Ritodrine hydrochloride is the only tocolytic agent that is currently approved by the Food and Drug Administration for this use. However, the clinical use of intravenous β-sympathomimetic therapy is somewhat limited by maternal side effects, development of tolerance, or lack of efficacy. Magnesium sulfate also has been widely used as a tocolytic agent. Prostaglandin synthetase inhibitors have been proposed as an effective alternative and often are used in cases in which either ritodrine or magnesium sulfate has failed.

The placebo-controlled studies with indomethacin have demonstrated an inhibitory effect on preterm labor,[1, 2] and one comparative trial of short-term therapy has shown efficacy equivalent to that of ritodrine.[3] In two additional randomized trials, the therapeutic effect of indomethacin was evaluated in combination with concurrent ritodrine therapy.[4, 5] In both studies the combined ritodrine-indomethacin treatment group had a significant prolongation of pregnancy when compared with that of the group treated with ritodrine plus placebo or with the group treated with ritodrine alone.

However, adverse effects in the neonate that result from the use of indomethacin have been of concern. Human and animal studies have shown transient ductal constriction,[6] although no long-term adverse effects on infants have been noted. Case reports have suggested an association between indomethacin treatment and primary pulmonary hypertension in the neonate,[7] but confounding factors such as sepsis or perinatal hypoxia may have contributed to the difficult neonatal adaptation in these cases. Primary pulmonary hypertension did not occur in the series reported with <48 hours of indomethacin treatment.[1, 3, 8-10]

The purpose of this randomized trial was to evaluate the efficacy and side effects of indomethacin compared with ritodrine for initial tocolysis and long-term treatment of preterm labor.

Material and methods

Forty-three patients who were between 23 and 34 weeks of gestation and who were treated at The Johns Hopkins Hospital or the Francis Scott Key Medical Cen-

ter for an initial episode of preterm labor with intact membranes were recruited between March 1987 and September 1988 for this study. This protocol was approved by the Joint Committee on Clinical Investigation at The Johns Hopkins University School of Medicine. All participating patients provided informed consent after receiving both written and oral presentations of the risks and benefits of each tocolytic agent to be used. Three randomized patients (7%) were excluded from this analysis. Two patients randomized to ritodrine therapy were eliminated before delivery as a result of protocol errors. One patient assigned to indomethacin therapy was eliminated soon after enrollment because of clinical, laboratory, and ultrasonographic evidence of a concealed abruptio placentae. The data for the remaining 40 patients were analyzed.

Patients qualified for the protocol if they were <34 weeks of gestation and had preterm contractions at a rate of at least 4 in 20 minutes or 8 in 60 minutes during the initial observation period. In addition, documented cervical change by a single examiner, initial cervical dilatation >2 cm, or effacement >75% was required for inclusion in the study. Subjects were excluded from the study if they presented with cervical dilatation >4 cm, or with rupture of membranes or if they had a cervical cerclage in place.

All participating subjects had cervical cultures taken for gonorrhea, group B streptococcus, chlamydia, and mycoplasma. Each subject underwent an ultrasonographic examination that included an amniotic fluid index.

Each patient was randomly assigned by a table of random numbers via a sealed envelope to either ritodrine or indomethacin treatment. Patients in the ritodrine group received the drug intravenously at a rate of 100 to 350 μg/min until contractions ceased. Maintenance intravenous fluids were administered at a rate of 125 ml/hr. Ritodrine was continued for 8 to 12 hours in the delivery suite after cessation of contractions before oral β-sympathomimetic therapy was started. Oral terbutaline was given in doses necessary to prevent recurrent uterine activity, titrated to a maternal heart rate of 80 to 100 beats/min, ranging from 2.5 to 5.0 mg every 4 to 6 hours. The choice of oral terbutaline as a maintenance tocolytic agent was made solely as a result of cost considerations.

Patients assigned to the indomethacin group received 125 ml/hr of maintenance fluid and were given an initial oral loading dose of 50 mg of indomethacin. Then indomethacin 25 to 50 mg was given orally at 4-hour intervals until contractions ceased; this protocol was continued for maintenance therapy at 25 mg orally every 4 to 6 hours. The initial treatment time spent by the indomethacin group in the labor and delivery suite was kept similar to that of the ritodrine group, in spite of different routes of drug administration.

In cases of successful initial tocolysis, study subjects were subsequently transferred to the antepartum ward and remained hospitalized on modified bed rest for an average of 2 to 3 days. A repeat four-quadrant amniotic fluid index was obtained before discharge in subjects receiving indomethacin; this fluid index was obtained weekly after discharge. All tocolytic agents were discontinued at 35 weeks of gestation.

Initial treatment failure was defined as progressive preterm labor that occurred in spite of maximum drug dosage or as patient intolerance that necessitated discontinuation of the original tocolytic agent. These patients then received intravenous magnesium sulfate with an initial bolus of 4 gm, which was followed by a continuous infusion at a rate of 2 to 4 gm/hr, and the initial tocolytic was stopped. Magnesium sulfate infusion was continued for 8 to 12 hours after the cessation of uterine contractions. If this therapy was successful, these patients were given the original agent assigned for subsequent maintenance oral therapy.

Patients with subsequent rupture of membranes, cervical dilatation >5 cm, or clinical evidence of chorioamnionitis or oligohydramnios were considered to be study failures. Patients with recurrent preterm labor were given intravenous ritodrine or increased oral indomethacin therapy according to their original assignment.

A review of nursing notes and a patient interview by one of the authors approximately 48 hours after delivery were used to assess drug-induced side effects. Mothers were asked if they would be willing to use their assigned tocolytic agents in future pregnancies as a gauge of patient acceptance. Unpaired *t*-tests and χ^2 test statistics were used to compare the data from the two treatment groups. Statistical significance was defined as a p value of <0.05.

Results

The two treatment groups were similar, except that the indomethacin group had a significantly higher number of elective pregnancy terminations (Table I). There were no statistically significant differences in the two groups with respect to maternal outcome (Table II).

A significant difference was observed in maternal symptoms (Table III). Whereas only one patient in the ritodrine group had intravenous therapy discontinued as a result of maternal intolerance, a large percentage of patients voiced complaints of side effects such as palpitations, jitteriness, lightheadedness, headache, and dyspnea. The incidence of gastrointestinal symptoms was similar in both groups.

Four-quadrant amniotic fluid index values remained constant in the study population that received indomethacin tocolysis. Weekly amniotic fluid estimations were performed for up to 63 days of tocolytic ther-

apy and failed to demonstrate a significant linear relationship between amniotic fluid volume and days of indomethacin administration (correlation coefficient = 0.17). Oligohydramnios was observed in a single fetus of a diamniotic twin gestation treated at 32 weeks. This infant's amniotic fluid index dropped for 10 to 2 cm during a 16-day course of indomethacin therapy. The other twin's amniotic fluid index values ranged from 7 to 10 cm.

The neonatal outcomes are presented in Table IV. There were no statistically significant differences in the two study groups.

Three neonates in the indomethacin group, two of whom were twins with discordant oligohydramnios, had clinical evidence of primary pulmonary hypertension shortly after birth. Serial ultrasonography had revealed lagging interval growth in both twins and oligohydramnios in twin B, but biophysical profiles were otherwise normal. Estimated fetal weights of both at 35 weeks of gestation were approximately 1500 gm. Oligohydramnios in twin B persisted 72 hours after discontinuation of indomethacin, and labor was induced for fetal indications. These twins were delivered by primary cesarean section after a second-stage arrest of labor and late decelerations in twin B (the infant with oligohydramnios). Twin A, a 1590 gm female, had an umbilical artery pH of 7.26. Twin B, a 1540 gm female, had an umbilical artery pH of 7.25. Each had 5-minute Apgar scores of 9 and each fell below the 10th percentile for weight at 35 weeks of gestation. Intubation in the delivery room was necessary in both twins and both began to have signs of pulmonary hypertension shortly

after admission to the neonatal intensive care unit. Twin A responded to hyperventilation therapy and was extubated on the second day of life without significant sequelae. However, twin B had a stormy neonatal course and required hyperventilation, tolazoline, and dopamine during 18 days of mechanical ventilation in the intensive care unit. Twin B was also treated with digitalization for a cardiomyopathy. Both twins were doing well at discharge.

The other patient whose infant had primary pulmonary hypertension presented in the twenty-fifth week of gestation and received indomethacin for 24 days before readmission with premature rupture of membranes. Amniotic fluid volume had been normal on three posttherapy ultrasonographic evaluations. The last dose of indomethacin was given approximately 8 hours before delivery of a 1240 gm female infant with a 5-minute Apgar score of 9 and an umbilical artery pH of 7.41. This neonate required immediate intubation and responded to hyperventilation for clinically apparent primary pulmonary hypertension. She subsequently required mechanical ventilation for 14 days and eventually needed indomethacin for closure of a patent ductus arteriosus.

Comment

This is the first randomized trial that compares long-term therapy with indomethacin and β-sympathomimetics. Our data suggest that these tocolytic drugs are comparable in delaying preterm delivery.

This study did not address the wisdom of tocolytic use in the treatment of preterm labor, although this has been questioned.[11] Because ritodrine is approved by the Food and Drug Administration for this indication and is widely used, we used it as the standard with which to compare indomethacin.

Morales et al.[3] recently reported a randomized trial

that compared short-term indomethacin with ritodrine for primary therapy in 106 preterm pregnancies. All undelivered patients were subsequently given oral β-sympathomimetic maintenance therapy until delivery. In that study delay of delivery for >48 hours was comparable in the two treatment groups, and no significant difference in gestational age at delivery or birth weight was reported. In addition, no significant differences in neonatal outcome were observed. A significant difference in maternal side effects was observed; 24% of the patients discontinued β-sympathomimetic therapy as a result of maternal intolerance. In the study by Morales et al., as in ours, no significant maternal side effects from indomethacin were reported. Drup-induced oligohydramnios was observed in 11% of the indomethacin group, which prompted discontinuation of therapy. A large cost differential between intravenous ritodrine therapy and short-term oral indomethacin therapy was also reported ($560 vs $33).

Our data on the difference in maternal side effects between these two tocolytic agents are similar to those of previous studies. Most patients that receive indomethacin are asymptomatic or have minor nausea or heartburn.[1, 10] Some patients receiving intravenous ritodrine report significant maternal cardiovascular and central nervous system side effects.[12]

Neonatal adverse effects have been reported previously with indomethacin therapy. Transient constriction of the ductus arteriosus has been reported,[6] which may be more common in fetuses of later gestation age. Case reports have suggested an association of indomethacin treatment with primary pulmonary hypertension.[7] However, large clinical experiences with short-term indomethacin therapy have failed to document such neonatal complications in a total of 584 exposed fetuses[1, 3, 8-10] who received the drug for ≤48 hours. However, Gerson et al.[13] observed two cases with complications among 31 fetuses exposed to long-term indomethacin therapy. Grella and Zanor[14] reported primary pulmonary hypertension in 4 of 29 infants, and Rubaltelli et al.[15] found five cases of pulmonary hypertension in 29 infants, all of whom were exposed to a 5-day course of indomethacin therapy. In our study the pulmonary hypertension in both fetuses of a twin pregnancy may have been attributable to long-term indomethacin therapy, but growth retardation is a confounding factor. The primary pulmonary hypertension in the other pregnancy is otherwise unexplained. In spite of these complications, all three neonates who experienced pulmonary hypertension are now alive without sequelae.

Recently, a number of clinical reports of indomethacin-induced oligohydramnios have appeared in the literature.[16, 17] In addition, indomethacin has been shown to reduce amniotic fluid volumes in pregnancies that are complicated by severe polyhydramnios.[18] This effect appears reversible with discontinuation of therapy and is probably a result of the ability of indomethacin to decrease fetal urine output.[17] The majority of the patients in our study who received long-term indomethacin therapy did not have oligohydramnios. The one case of nonreversible oligohydramnios observed in a complicated twin gestation was probably the result of growth retardation. Oligohydramnios is dose dependent[16] and occurs more frequently at a dosage of 200 mg of indomethacin per day but not at 100 mg per day, which most of our patients received.

We conclude that indomethacin is as effective as the β-sympathomimetics for tocolysis, although this study was discontinued before the numbers reached a level necessary to minimize type II error. We had not previously seen primary pulmonary hypertension when we limited indomethacin therapy to 24 to 48 hours. Thus we speculate that if indomethacin treatment is prolonged for >48 hours, there may be an increased risk of this complication.

Discussion

DR. THOMAS H. KIRSCHBAUM, Los Angeles, California. This article extends a related study published in 1980.[1] In the earlier work, which was a randomized blind study, the efficacy of indomethacin in inhibiting preterm labor was compared in two groups of patients: those treated with indomethacin and those who did not receive indomethacin. The study was not placebo controlled in a rigorous sense, because 30% of the women in the control group ultimately received other tocolytic drugs. Entry criteria were virtually the same as in this study. Treatment failure was defined as a progressive change in the cervix that occurred >2 hours after initial treatment or the attainment of >4 cm of cervical dilatation. Fifteen patients were studied in each group, and there was a statistically significantly larger incidence of treatment failure in the control group as opposed to drug-treated patients at 24 and 48 hours after the initiation of therapy. No effect on outcome as measured by life-threatening newborn complications or perinatal death was seen, although the numbers of cases were relatively small. Mean values indicate that the drug-treated group averaged 3.2 weeks of prolongation of pregnancy after treatment, whereas the control group averaged 3.0 weeks of prolongation.

In this article the authors make two points. The first is that indomethacin is less expensive than ritodrine, has fewer maternal side effects, and is as effective as ritodrine, as the outcome measurements indicate. The second point is that pulmonary hypertension was seen in two of the pregnancies and in three of the infants of 22 women who received indomethacin, whereas none of the 18 women treated with ritodrine experienced those neonatal complications. There are, I believe, some questions that concern the validity of those conclusions, and I should like to pose two additional questions.

The differences in the reproductive histories of the two study groups are regrettable because they constitute uncontrolled variables. Eighteen of the ritodrine-treated women had 20 prior pregnancies, which included seven abortions; 22 of the women treated with indomethacin had 52 prior pregnancies, which included 26 abortions. The interval to delivery and hence of drug therapy for both groups shows a great deal of scatter from the respective means. I calculate a mean and SD of 27.9 ± 22.9 days for ritodrine and 25.5 ± 20 days for indomethacin. Whether the unpaired *t* test might not be misleading for differences between means when frequency distributions are not in a gaussian curve is a serious question. Also, these results were obtained with the use of magnesium sulfate in about 30% of both groups after the initial drug failed to control labor. This means that a comparison of the effects of indomethacin and ritodrine alone cannot be made from these data. In fact, the data suggest bimodal or multimodal frequency distributions. This problem is further exhibited in the authors' Table IV, in which the 8.9 average number of days on the ventilator for the infants born to women treated with ritodrine has a standard deviation of 13.9 days. This indicates a number of extreme outliers form the mean value. Again, the choice of the statistical analytic technique used here is questionable.

These factors do not help to prove a negative hypothesis—here, that there is no difference between these two forms of therapy. This premise differs from that of the article written in 1980, in which a positive hypothesis was pursued. A negative hypothesis can never be proved; it simply displays the experimental design, the number of cases studied, and the data analysis and makes the argument that if there were a difference, it would have been discerned. In this study all three of those elements are arguable. As the authors acknowledge, the number of cases studied is too small to minimize the chance of false-positive errors or β-errors. The presence of a difference between these two forms of therapy might have been seen if more cases had been studied or, for example, if a design that included no magnesium sulfate therapy had been used.

Would such a study have been ethically acceptable? I think so, if the work of others in this area is examined. The authors' 1980 article is one of two studies that purport to show the effects of indomethacin in inhibiting labor for at least 24 hours.[1, 2] Two other studies show that the effect of indomethacin tended to delay labor for 48 hours[2, 3] without effect on fetal and neonatal deaths (five studies[1-5]) or respiratory distress syndrome (four studies[1, 2, 4, 5]). β-Sympathomimetic tocolysis has been shown to be effective in delaying the delivery of infants in treated patients (as compared with control subjects) for 24 hours (five studies[6-10]) or for 48 hours (two studies[9, 10]) without affecting perinatal mortality (14 studies[6-10]) or respiratory distress syndrome (12 studies[7-10]). It is a recurring observation that data in this area fail to show an effect on morbidity or survival, and in the absence of that evidence of benefit, not treating patients would seem to be acceptable. The maintenance of pregnancy with oral β-sympathomimetic agents has not been shown to be of

value, and no data exist in regard to the effectiveness of oral maintenance doses of prostaglandin synthetase inhibitors.

A final question relates to the average time of nearly 1 month that elapsed between treatment and delivery in these patients. The question, of course, is whether these patients were ever truly in preterm labor. Entry criteria consist of uterine contractions that occur roughly every 5 to 7½ minutes, cervical change, or a cervix with dilatation >2 cm or effacement >75%. It is hard to know what constitutes 75% of normal effacement, particularly in multiparous women, and the term *change* allows subjective evaluation. All of us have seen patients who were clearly not in labor but who met the entry criteria. Until direct biochemical markers of labor appear, this question will continue to make good experimental design, large numbers of cases, and careful statistical evaluation essential.

The data allude to the effect of long-standing indomethacin treatment on ductus arteriosus stenosis and resultant pulmonary hypertension. Ductal patency is dependent on the production of large amounts of prostaglandins by the ductus endothelium and muscularis. Inhibition of uterine contractions with indomethacin in fetal animals and in human neonates has been demonstrated to constrict the ductus and to produce fetal pulmonary hypertension with possible neonatal consequences. Two of 22 treated with indomethacin constitute evidence that suggests that the risks of indomethacin treatment may be greater than the benefits. The use of indomethacin without clear evidence of benefit beyond the prolongation of pregnancy by 24 to 48 hours may be seriously questioned.

The authors have added new data that address this important area. Regrettably, they have not provided a great deal of clarification as a result of the intrinsic difficulty of research in which labor cannot rigorously and objectively be defined.

DR. DAVID COTTON, Houston, Texas. I have some comments and then a question. As you know, Dr. Moise in our group has been very interested in the effects of indomethacin on the fetus. Because of his work that associates closure of the fetal ductus and oligohydramnios with indomethacin treatment of pregnant women, we have a rather cumbersome protocol for follow-up of these patients. In that protocol we evaluate ductal patency once a week and assess amniotic fluid volume twice a week.

We have seen the occurrence of fetal ductal closure and tricuspid insufficiency within about 48 hours of the initial administration of indomethacin, and we have also seen tricuspid insufficiency that did not resolve in 48 hours. In one case tricuspid insufficiency actually lasted 3 days but did finally resolve. Thus the adverse effects of indomethacin can sometimes be seen fairly quickly.

We have never been able to define the timing of amniotic fluid reduction. In some women a reduction in amniotic fluid volume develops after only 3 or 4 days of indomethacin therapy. Other patients will be treated with indomethacin for as long as 3 weeks before a decrease in amniotic fluid results. We still feel that it is very important to monitor amniotic fluid volume in patients, because we have had some evidence that neonatal renal failure may occur in women who have had prolonged oligohydramnios.

However, the side effects described in this study pertain to those in the β-sympathomimetic group that are usually seen very early on and that in many instances start to decrease over a 3-day to 7-day period if the patient becomes asymptomatic. Terbutaline may continue to have its effect of relaxation of the uterus.

Amniotic fluid must be measured on a regular basis via ultrasonography. The side effects of a medication may initially be more complicated to follow, but after an initial evaluation, sophisticated monitoring is not required, even if the ductus is not evaluated. Do you think these agents really are comparable in terms of how easy and how expensive they are for the patients to take them?

DR. ROBERT RESNIK, San Diego, California. Several years ago, Dr. Irwin Merkatz wrote a multiinstitutional collaborative study on the effects of ritodrine, which led to the approval of ritodrine by the Food and Drug Administration. As I recall (and he may wish to comment on the clarity of what I'm going to say), the mean

number of days gained before delivery in the control group was 21. In Dr. Niebyl's study the mean was 25 days in the indomethacin group and 28 days in the ritodrine group.

Would you comment on this, in light of Dr. Kirschbaum's previous comments, and define the onset of true labor to aid in determining the efficacy of these drugs?

Dr. Warren M. Crosby, Oklahoma City, Oklahoma. The neonatologist who treats primary pulmonary hypertension in which the ductus remains open is in a real bind, because once he or she closes the ductus, the pulmonary hypertension becomes worse. This study does not comment on the three babies that were treated in that manner. I would like to know if those babies became clinically better or worse.

Dr. Thomas J. Garite, Orange, California. We have just completed an analysis of some data and have found an interesting association between indomethacin and necrotizing enterocolitis. Did you see any cases of necrotizing enterocolitis in your group?

Dr. Niebyl (Closing). First of all, I'll try to answer Dr. Kirschbaum. His questions about the statistics are well taken, but I think that we used the appropriate tests for the number of patients. We had only 40 patients, and I think that applying a more sophisticated method might have gotten us into trouble.

The point about untreated controls is an important one that several people have reiterated. We had originally done a placebo-controlled trial with indomethacin, which showed that indomethacin treatment was effective, at least during that 48 hours of therapy. The important questions really concern the effectiveness of indomethacin in prolonging pregnancy or in making a significant difference in the health of the baby. I'm not sure that it does.

The reason we designed this trial, in which patients receive treatment with the drug for a month, was really to answer those questions. This study was simply a comparative study of the effects of ritodrine and indomethacin treatment. The study was not done to examine the whole issue of whether untreated control subjects do as well as drug-treated subjects.

I think that the answers may be somewhere in the middle; a certain subgroup of patients will benefit from treatment, but there are also certain patients who are undoubtedly not in preterm labor and who, if left untreated, would not be delivered of their infants. It's very difficult to identify those patients. We certainly know that patients who come in repeatedly for examinations and who do not experience cervical change are still at risk of preterm delivery. Thus there are some groups of patients who may benefit.

There's certainly a placebo effect if all of the placebo-controlled trials or untreated control trials are examined. There is a success rate of 20%, 30%, or sometimes even as high as 50% to 60% in avoiding preterm delivery without treatment. Our problem is the difficulty in diagnosing which patients are really in preterm labor.

Dr. Cotton mentioned the work on Doppler ultrasonography by the group at Baylor. I think that if I were designing this study to start today, I would incorporate some sort of Doppler follow-up with these babies, because as the Baylor study indicates the constriction can happen very quickly. We did monitor amniotic fluid volume. We did not look at the ductus. Dr. Cotton's question really related more to which medication is the more difficult to use. I think his point that ritodrine is more difficult to use initially is well taken. Tachycardia or other problems may result immediately with ritodrine treatment, but tolerance to the medication may develop in a patient with long-term therapy. I feel that trouble with indomethacin may occur in long-term therapy, as it did in the few cases that we reported.

Dr. Crosby asked me whether infants who had primary pulmonary hypertension in which the ductus remained open improved after closure of the ductus. All those babies responded very well, did well in the nursery, and went home without problems. They were sick initially, but they did respond to therapy and did not have any significant long-term problems.

Dr. Garite asked about necrotizing enterocolitis. We didn't see any, but the association has been reported in the literature. However, this type of enterocolitis does not occur often, and there has been no significant association of the disease with indomethacin treatment.

The induction of premature luteolysis in normal women—follicular phase luteinizing hormone secretion and corpus luteum function in the subsequent cycle

Michael R. Soules, MD,[a] William J. Bremner, MD, PhD,[b, c] Kristine D. Dahl, PhD,[b, c] Jean E. Rivier, PhD,[d] Wylie W. Vale, PhD,[d] and Donald K. Clifton, PhD[a]

Seattle, Washington, and La Jolla, California

Women with luteal phase deficiency have been shown to have an increased frequency of luteinizing hormone pulses in the early follicular phase of the menstrual cycle. Because progesterone is known to modulate luteinizing hormone secretion, it has been hypothesized that the decreased progesterone secretion in a previous luteal phase deficiency cycle could lead to the abnormal luteinizing hormone secretory pattern in the ensuing early follicular phase. With the possibility that the higher luteinizing hormone pulse frequency might lead to another deficient luteal phase, it becomes conceivable that luteal phase deficiency could be self-perpetuating. To test this hypothesis, luteal phase deficiency was induced in six normal women by decreasing luteinizing hormone support of the corpus luteum with a gonadotropin-releasing hormone antagonist Nal-Glu, administered twice daily beginning in the midluteal phase after a control cycle. During the antagonist-treated luteal phase, each subject met the predetermined criteria for induced luteal phase deficiency: a 33% or greater decrease in integrated progesterone from the control cycle and an integrated progesterone level <100 ng/ml per day. Luteinizing hormone secretion patterns were determined by frequent blood sampling performed every 10 minutes for 12 hours in the early follicular phase of the control cycle and the cycle after antagonist administration. Daily luteal progesterone levels were measured in the control, treatment, and posttreatment cycles. Each volunteer served as her own control. Standard parameters were compared between the control and posttreatment pulse studies in the early follicular phase: (1) luteinizing hormone pulse frequency was 9.5 ± 1.0 vs 10.0 ± 0.9 pulses/12 hours, control vs posttreatment, respectively, $p = 0.5$; (2) luteinizing hormone pulse amplitude was 11.0 ± 1.3 vs 12.0 ± 2.2 ng/ml, $p = 0.6$; and (3) luteinizing hormone mean level was 19.4 ± 2.3 vs 22.2 ± 3.3 ng/ml, $p = 0.1$. Corpus luteum function was also compared between the control and posttreatment cycles. Luteal phase length was 13.7 ± 0.6 vs 12.7 ± 0.6 days, $p = 0.08$. Integrated progesterone values were 136.9 ± 12.9 vs 130.5 ± 11.3 ng/ml per day, $p = 0.5$. Therefore no discernible abnormalities in early follicular luteinizing hormone secretions or corpus luteum secretion of progesterone occurred after an induced luteal phase deficiency cycle. We conclude that luteal phase deficiency is not self-perpetuating and that the rapid luteinizing hormone secretion pattern found in the early follicular phase in women with luteal phase deficiency is not a result of decreased progesterone levels in the preceding luteal phase, but rather appears to be a result of dysfunctional suprahypothalamic neuroendocrine modulation of the gonadotropin-releasing hormone pulse generator. (Am J Obstet Gynecol 1991;164:989-96.)

There is a complex relationship between the hypothalamic-pituitary (neuroendocrine) unit and the corpus luteum in women. A well-described shift in luteinizing hormone (LH) pulse frequency and amplitude occurs from the follicular to the luteal phase, with fewer LH pulses of higher amplitude present in the second half of the cycle. This slowing of the LH secretion pattern in the luteal phase is a result of progesterone feedback on the hypothalamic gonadotropin-releasing hormone (GnRH) pulse generator, which is mediated by endogenous opioid peptides.[1, 2] Progesterone secretion by the corpus luteum is pulsatile as well and has been shown to be coupled with LH pulses in the midluteal

and late luteal phases.[3-5] LH appears to be required in both a permissive and a quantitative manner for normal progesterone secretion by the corpus luteum.[3, 6] Because the follicular phase LH pulse pattern is of relatively high frequency and low amplitude, there is a necessary increase in the LH secretory rate that accompanies the death of the corpus luteum. Withdrawal of progesterone is the presumptive stimulus for the luteal to follicular increase in gonadotropin pulse frequency.

Luteal phase deficiency is a well-described aberration of the menstrual cycle that usually consists of decreased progesterone secretion by the corpus luteum. Luteal phase deficiency can be a phenomenon that occurs sporadically in normal women, without clinical significance, or it can be the cause of infertility or habitual abortion.[7] We have reported significant abnormalities in the hypothalamic-pituitary-ovarian axis in women with luteal phase deficiency. They have an increased LH pulse frequency in the early follicular phase, decreased mean LH levels during the LH surge, decreased bioactive LH levels in the midluteal and late luteal phases, and decreased progesterone pulse amplitude in the luteal phase, accounting for their low integrated progesterone levels.[8, 9] In a separate study we were able to produce luteal phase deficiency in normal women by inducing a supraphysiologic LH pulse frequency during the follicular phase.[10] On the basis of these studies, we consider the rapid early follicular LH pulse pattern a key element in the pathophysiology of luteal phase deficiency and believe it is the probable cause of the abnormal LH and progesterone secretion later in the cycle.

Thus with our focus on the rapid early follicular LH pulse pattern as a key element in the pathogenesis of luteal phase deficiency and the ability of progesterone to modulate the LH pulse frequency, we hypothesized that luteal phase deficiency could be self-perpetuating. The following hypothesis was entertained: decreased progesterone secretion in a given luteal phase could result in an excessively rapid gonadotropin pulse pattern in the subsequent follicular phase which, in turn, would lead to luteal phase deficiency in that and future cycles. This study was designed to test this hypothesis. To this end, luteal phase deficiency (premature luteolysis with decreased luteal progesterone levels) was induced in normal women with a GnRH antagonist and the subsequent cycle was monitored in terms of the follicular LH secretion pattern and corpus luteum function.

Methods

Subjects. This study was designed for normal volunteers to serve as their own controls. These women ($n = 6$) were between 26 to 33 years of age, within ±10% of their ideal body weight (Metropolitan Life Insurance Co. tables, 1980), and no more than moderate exercisers. They had a history of 27- to 32-day menstrual cycles, at least one normal biphasic basal body temperature chart, and met the following hormonal criteria in the midluteal phase of a menstrual cycle preceding the study: progesterone ≥12 ng/ml, prolactin <20 ng/ml, and testosterone ≤40 ng/dl. The protocol was approved by the Human Subjects Committee of the University of Washington and informed consent was obtained from each woman.

There was a preset criterion for inclusion in the study that the GnRH antagonist administration induce a luteolysis sufficiently similar in terms of the pattern and time course of decreased progesterone levels to that seen in women with spontaneous luteal phase deficiency as previously described.[8] To this end, we required each subject to have a luteal phase of 13 or more days and an integrated progesterone level >100 ng/ml per day in the control cycle. In the luteal phase of the treated cycle they had to have an integrated progesterone level <100 ng/ml per day that was also a minimum of 33% below the integrated progesterone in their control cycle. Whereas a more profound and dramatic luteolysis could have been achieved with the Nal-Glu GnRH antagonist, depending on the dose, the decreased progesterone levels observed in spontaneous luteal phase deficiency cycles tend to be modest (around 33%) and usually occur in the latter half of the luteal phase. Some women with luteal phase deficiency had entirely normal levels of progesterone until the midluteal phase.[8] Fifteen subjects volunteered for the study and six met the criteria. Of the subjects who did not meet the study criteria, five had low integrated progesterone levels in the control cycle and the other four had insufficient luteolysis.

Protocol. The study encompassed three menstrual cycles. The protocol is summarized in Fig. 1. Daily blood samples were obtained from cycle day 10 until the onset of the next menstrual period in all three cycles. These samples were allowed to clot, serum was separated, aliquoted, and frozen at −4° C until assayed for LH and progesterone. A 12-hour admission to the Clinical Research Center occurred in the early follicular phase (cycle days 1 to 4) of the second and third study cycles. During these admissions (8 AM to 8 PM) a heparinized intravenous line was placed, through which 5 ml venous blood samples were drawn every 10 minutes (total, 73 samples). The serum from these samples was frozen at −4° C and subsequently assayed for LH.

The Nal-Glu antagonist injections were initiated in the midluteal phase of study cycle two and were administered subcutaneously every 12 hours. The injections began on cycle days +5 or +6 in relation to the LH surge (day 0) and were continued until the onset of the next menstrual period. The dose of the Nal-Glu

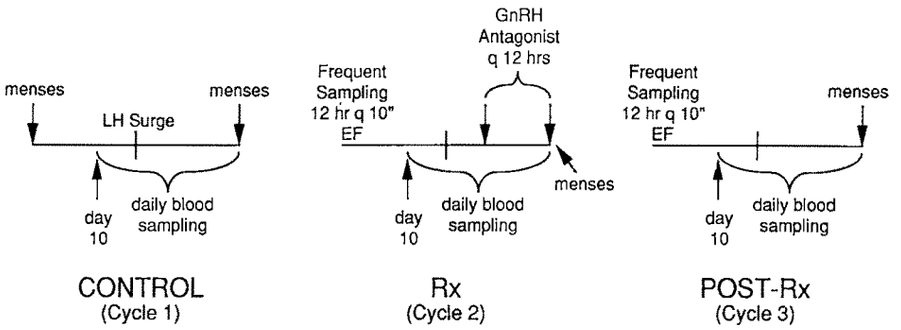

Fig. 1. The study protocol encompassed three menstrual cycles. The luteal phase of cycle one and the early follicular *(EF)* phase of cycle two were control intervals for luteal progesterone and follicular LH secretion, respectively. Luteal phase deficiency was induced with a GnRH antagonist administered from the midluteal phase of cycle two until the subject's next menstrual period (*Rx*, treatment). LH and progesterone secretion were monitored in cycle three.

antagonist was determined on the basis of our previous experience with its administration in the luteal phase[11] and was either 2.5 μg/kg or 5.0 μg/kg for each injection. The daily blood sampling increased to every 12 hours during antagonist administration, which varied between 5 and 8 days in duration.

Assays. Serum LH was measured by double antibody radioimmunoassay as previously described[12] with reagents supplied by the National Institutes of Health with LER 907 as the reference preparation. The sensitivity of the LH assay was 6 ng/ml, with intrassay and interassay coefficients of variation of 5.5% and 8.4%, respectively.

Serum progesterone was measured by radioimmunoassay with reagents supplied by Diagnostic Products Corp. (Los Angeles). This assay had a cross-reactivity of 0.3% with 17-hydroxyprogesterone and <0.01% with testosterone, estradiol, pregnenolone, and cortisol. The assay sensitivity was 0.5 ng/ml, and intraassay and interassay coefficients of variation were 9% and 12%, respectively.

Statistics. Luteal phase length in this study was defined as the number of days that occurred subsequent to the LH surge (peak LH value, day 0) and before the next menstrual period. Integrated progesterone values were calculated for each subject's luteal phase by adding the daily serum progesterone levels together beginning with the day of the LH surge; they are expressed as nanograms per milliliter per day.

For each subject there were 73 LH data points from the early follicular phase admissions in study cycles two and three. The following pulse parameters were calculated for LH: frequency, amplitude, and mean level. An adaptive threshold method (DC3) was used to determine the frequency and amplitude of pulses as previously described.[13]

Each volunteer served as her own control. Comparisons were made between study cycles with the paired Student t test for luteal length, integrated progesterone, and pulse parameters. The data are presented as mean ± SEM unless otherwise indicated. A p value ≤ 0.05 was considered significant.

Results

A decrease in serum progesterone levels in cycle two that simulated luteal phase deficiency was a requirement of this study. Thus mean integrated progesterone levels over the luteal phase decreased from 136.9 ± 12.9 to 80.7 ± 7.2 ng/ml per day between the control and treatment cycles (Fig. 2). Not unexpectedly, mean luteal phase length also decreased from 13.7 ± 0.6 to 11.2 ± 0.8 days ($p < 0.01$) between the control and treated cycles (Fig. 2). Therefore a luteal phase deficiency–like condition was successfully induced in these normal women.

The posttreatment cycle was carefully examined to ascertain whether this luteal phase deficiency state had a carry-over effect(s) into the subsequent cycle. The LH pulse pattern in the early follicular phase of the posttreatment cycle was compared with the pattern before treatment. A representative pair of early follicular LH secretion patterns from a particular volunteer are illustrated in Fig. 3. Both patterns appear to represent normal early follicular LH secretion. In fact, when the LH secretory parameters were compared for the entire group, there were no differences in frequency, amplitude, or mean level between the control and posttreatment sampling intervals (Table I).

In terms of luteal phase length and serum progesterone levels, the posttreatment cycle was similar to the control cycle. There was a tendency toward a decreased mean luteal phase length (12.7 ± 0.6 vs 13.7 ± 0.6 days, respectively, $p = 0.08$, Fig. 2). However, the mean integrated serum progesterone levels were nearly iden-

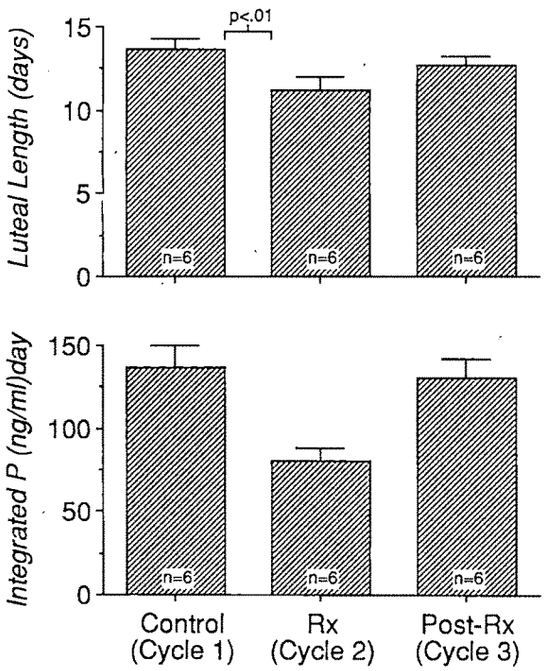

Fig. 2. Corpus luteum function in each of the three cycles is illustrated. Luteal phase deficiency was successfully induced in the treatment *(Rx)* cycle.

tical at 130.5 ± 11.3 vs 136.9 ± 12.9 ng/ml per day, $p = 0.5$ (Fig. 2). Therefore there was no evidence of a luteal phase deficiency–like condition in the posttreatment cycle.

Comment

Luteal phase deficiency is both a controversial and a diverse disorder with a number of investigators debating whether it actually occurs. It certainly does exist because it has been well documented in many different settings: post menarchal[14]; premenopausal[15]; post partum[16]; with strenuous exercise[17]; with dieting[18]; and in "normal" women who volunteer as control subjects.[19,20] It can be induced by interfering with folliculogenesis,[21] luteal phase luteinizing hormone suppression,[22] or a supraphysiologic early follicular LH pulse frequency.[10] Therefore the relevant question is not whether it exists, but does it occur regularly in some women and thereby cause infertility or recurrent abortions? The latter question remains controversial, primarily because there is not a simple effective test to determine whether luteal phase deficiency is present in the clinical setting.[23] It is our considered opinion that luteal phase deficiency is a primary cause of infertility and habitual abortion in 5% to 10% of a population referred for subspecialty care.

Luteal phase deficiency consists of either decreased corpus luteum function (inadequate secretion of progesterone, estradiol, and inhibin) or an insufficient hormonal effect at the level of the endometrium. Whereas considerable research attention has been directed at insufficient end-organ response in luteal phase deficiency, very little consistent evidence has come forth.[23] Therefore in both the research and clinical setting, luteal phase deficiency as we understand it today can primarily be characterized as inadequate hormonal secretion. Many reasons for inadequate hormonal secretion by the corpus luteum have been proposed: (1) inadequate follicular development, (2) a dysfunctional LH surge, (3) insufficient LH support of the corpus luteum in the luteal phase, (4) endogenous corpus luteum defect(s) that preclude adequate function, and (5) premature or excessive luteolysis.

There has been a relative paucity of studies that have investigated the pathogenesis of spontaneous luteal phase deficiency in women, especially with regard to endogenous defects in the corpus luteum itself. There are good indications that interference with folliculogenesis can lead to luteal phase deficiency[21] and abnormal follicular phase follicle-stimulating hormone (FSH) levels have been reported in luteal phase deficiency.[19,20,24] However, we were not able to find any abnormalities in FSH levels, follicle size, or estradiol levels in an in-depth study of 10 women with sponta-

neous luteal phase deficiency.[8] That study did find deficiencies in the LH surge and in the LH support of the corpus luteum. We believe this lack of hormonal stimulus to the corpus luteum is a major component of the pathophysiology of luteal phase deficiency. In addition, two further pieces of evidence led us to focus on the neuroendocrine component (GnRH pulse generator) as the basis for luteal phase deficiency in most women with this condition. First, we have quite consistently found a significant increase in LH pulse frequency (with the expected decrease in LH pulse amplitude) in the early follicular phase of luteal phase deficiency cycles.[9] Other investigators have found abnormalities (both rapid and slow) in early follicular LH pulse frequency in luteal phase deficiency as well.[25, 26] Second, we were able to induce significantly decreased luteal phase levels of progesterone and bioactive LH in normal women by means of a supraphysiologic LH pulse frequency in the follicular phase.[10] Therefore it appeared to us that investigating the altered GnRH pulse generator in the follicular phase might be the key to understanding the pathophysiology of luteal phase deficiency.

One possible cause of the increased secretory rate of LH in luteal phase deficiency could be the low progesterone levels in the prior luteal phase. Progesterone is known to modulate (slow) the GnRH pulse generator,[1] thus too little progesterone could lead to a premature and excessive increase in LH secretion and, potentially, luteal phase deficiency in the next cycle. This study found no compelling evidence that luteal phase deficiency perpetuates itself into subsequent cycles. The lack of decreased progesterone secretion was to be expected after induced luteal phase deficiency when no changes in the LH secretory pattern in the early follicular phase occurred. It now becomes necessary to look at other modulators of the GnRH pulse generator to understand the alterations in early follicular LH secretion and the pathophysiology of luteal phase deficiency. There are many examples of suprahypothalamic influences on the GnRH pulse generator that have profound effects on the menstrual cycle. Conditions such as anorexia nervosa,[27] hypothalamic amenorrhea,[28] heavy exercise,[29] and dieting[30] all have in common either psychological or physical stress, abnormal gonadotropin secretion patterns, and menstrual dysfunction. We postulate that luteal phase deficiency as a mild and subtle form of menstrual dysfunction commonly occurs because of stress-induced alterations in the GnRH pulse generator, mediated by neurotransmitters.

We gratefully acknowledge the laboratory assistance of Dorothy McGuinness, Florida Flor, and Arlen Sarkissians; the illustration assistance of Jan Hamanishi and Patrick Clarke; the data analysis of Dawn McCracken; and the editorial assistance of Nancy Cohen.

Discussion

Dr. Isaac Schiff, Boston, Massachusetts. Dr. Soules is clearly a leader in the field of luteal phase deficiency. His solid and important research has furthered our knowledge of the subject since Dr. Georgeanna Seegar Jones first described the condition over 40 years ago. Luteal phase deficiency was defined as the unusual condition in which the endometrium was greater than 2 days out of phase as documented by endometrial sampling. The treatment that was suggested was progesterone supplementation. Numerous studies that indicate the beneficial results of progesterone therapy for luteal phase deficiency, when traditionally diagnosed with a biopsy specimen, constitute provocative evidence for this disorder being a cause of reproductive failure.

I read Dr. Soules' article with great interest and in the brief time allowed me here I would like to formulate my comments on it in a number of questions—it being true that every scientific article of significance raises as many questions as it answers.

His protocol asked whether normal women can withstand an assault on their hypothalamic pituitary gonadal axis by internally adapting and resetting the pulse generator. The answer to the posed question was clearly no. There was no evidence of induction of a luteal phase deficiency–like condition. Perhaps some persons are more susceptible to hypothalamic pituitary gonadal axis perturbations than are others. Is it true that most persons with some stress or external stimuli can adapt and reorganize the hypothalamic pituitary gonadal axis

for the next menstrual cycle and therefore resist the tendency of luteal phase deficiency to develop? Is it true that others cannot because of some defect of the hypothalamic pituitary gonadal axis that, although subtle, is serious enough to produce luteal phase deficiency? One could thus obtain different data if more patients were studied or if an infertile group of women were so examined. After all, the authors state that luteal phase deficiency can be a phenomenon that occurs sporadically in normal women. On this same matter, how long do the effects of alteration in progesterone persist to control gonadotropin secretion?

In his article, Dr. Soules stresses the LH pulsations as an explanation for luteal phase deficiency. Given the unfair advantage of hindsight and being cognizant of the negative results, one might ask whether there is too much emphasis on LH. According to the work of Hutchison, the corpus luteum can be maintained with infrequent pulses of GnRH (hence LH) during the luteal phase, but its usual duration cannot be extended with physiologic doses. And indeed other factors such as prostaglandins may be operative. High levels of LH in the follicular phase may induce multiple folliculogenesis, and the increase in estrogens from these follicles could produce premature luteinization and the corpus luteum defect. Could, then, the addition of LH in the luteal phase prevent luteal phase deficiency? Finally, if LH is that critical then it implies that the hypothalamus pituitary-luteal axis is homeostatic, as are other pituitary target organs. I think that this is not the case, and it is a good thing too, because then the pituitary would always be trying to rescue the corpus luteum at the end of each nonconception cycle.

Some authors believe that luteal phase deficiency might be induced by an alteration in FSH levels in the follicular phase. Dr. Soules, did you happen to measure FSH, and if so, did you find a difference?

In the day-to-day clinical situation, many physicians do not have access to Dr. Soules' laboratory expertise, and they are compelled to rely on results of endometrial biopsies. Given their well-known drawbacks, I wonder whether in carrying out his study Dr. Soules performed any biopsies?

To induce experimentally the condition of corpus luteum defect, the investigators used a GnRH antagonist. The procedure, as the authors acknowledge, shortens the luteal phase. The short luteal phase might itself be only one type of corpus luteum defect. A further reaching study design would have called for a luteal phase of 12 to 14 days' duration and an integrated progesterone level that is decreased. I welcome Dr. Soules' suggestions on this point.

Perhaps there is another conceptual framework for the model of the self-perpetuating nature of luteal phase deficiency. If we assume that the following statements are more or less basic observations: (1) progesterone in nonconception cycles declines at some point and (2) the pulse generator does not count the days from the LH surge and it does not act differently when luteolysis occurs early, inasmuch as it always has to recover from a fall in progesterone to renew the state of estrus, I wonder whether Dr. Soules would comment about a classic homeostatically oriented hypothesis that would theorize that follicular recruitment and subsequent luteal function would if anything be more robust after a short, insufficient luteal phase.

In summary, Dr. Soules has achieved remarkable results in the delineation of luteal phase deficiency. His careful, meticulous studies led him to reason that decreased progesterone in the luteal phase might alter LH pulsatile secretion in the subsequent follicular phase. The idea constituted a brilliant attempt to consolidate a pathophysiologic vision about a difficult question in a single study. Unfortunately, this did not turn out to be the case. Therefore decreased progesterone production in one cycle does not lead to recurrent luteal phase defects in normal women, implying important evidence that supports the complex cause of this syndrome. Thus we will await with great expectations his follow-up studies that may shed further light on the matter.

Dr. James Schreiber, Chicago, Illinois. The hypothesis was that low progesterone would set off the next cycle to make it short. I was curious whether another way to approach this would be to use an antiprogestin such as RU 486, mifepristone, and block progesterone directly rather than perturbing centrally with the GnRH antagonist.

Dr. Daniel H. Riddick, Burlington, Vermont. I wonder whether you have looked at the converse of your experimental design. Have you taken women with luteal phase deficiency and supplemented the progesterone to normal levels in a deficient cycle and then studied the subsequent cycle with no treatment in those women?

Dr. Soules (Closing). I thank Dr. Schiff for a very thorough review of the article and his thoughtful questions.

The first question was in regard to the time course of effect of altering progesterone on LH secretion. The LH pulse generator (the gonadotropin generator) accelerates when progesterone is not present. On the basis of our studies and the literature, when progesterone levels decrease in the midluteal to late luteal phase, the LH pulse generator speeds up. The increase in the LH secretory takes place over 2 to 4 days.

He brought up a good point: we did not necessarily prove the null hypothesis by studying only six women. We could have studied more women and found that our hypothesis was actually true or we could have stud-

ied more susceptible women (e.g., infertile women) and may have found that our hypothesis was true. That is a good criticism. However, I happen to doubt that the study of more or different subjects would have changed our findings because we did not even see a trend in our data toward luteal phase deficiency in the menstrual cycles after induced luteolysis.

Dr. Schiff asked whether addition of LH in the luteal phase could prevent luteal phase deficiency. Yes, I believe it can. In fact, human chorionic gonadotropin supplementation is an acceptable therapy for luteal phase deficiency. It is not used very often; but in my experience, human chorionic gonadotropin does work.

The fourth question was provocative in regard to the pituitary and whether it had a homeostatic relationship with the ovary. His example was the pituitary-thyroid axis wherein the pituitary does everything it can to keep the end organ functioning when it fails. I think the pituitary ovarian axis functions in the same manner. In the late luteal phase when there is the normal decrease in progesterone, the gonadotropin pulse generator accelerates with a corresponding increase in the mean levels of LH and FSH. The hypothalamic pituitary unit is trying to rescue the corpus luteum, but the corpus luteum remains resistant. Therefore the pituitary does act in its usual homeostatic manner with the ovary as well.

The next question was whether we measured FSH in these particular patients. The answer is no, but I would like to allude to our 1989 study in which we intensively studied 10 women with spontaneous luteal phase deficiency. In that study, we looked at FSH every way we could to determine whether there were any changes in FSH. We looked at immunoactive FSH, bioactive FSH, follicular size, and estradiol levels. In these infertile women with spontaneous luteal phase deficiency, we could not find any evidence that abnormalities in FSH or follicular development were a part of the pathogenesis of luteal phase deficiency. However, it is clear in the literature that altering FSH or follicular development can cause luteal phase defect.

The next question was with regard to biospies. No, we did not obtain endometrial biopsy specimens because we think the integrated progesterone level provides a much more accurate diagnosis of luteal phase deficiency.

Dr. Schiff's next question was whether we could have induced a different type of luteal phase deficiency (low progesterone levels but with normal luteal length). This is the most common pattern we see in spontaneous luteal phase deficiency. It would have been nice to induce this pattern, but our experience with the Nal-Glu GnRH antagonist is that you can not be that precise. In fact, we experienced the opposite problem of luteolysis being induced too quickly, wherein we dropped the bottom out of the corpus luteum immediately in some dose studies that preceded this study. So I think more prolonged luteolysis would have been a nice study design, but this was beyond the capabilities of our study drug.

The next question concerned our hypothesis. Dr. Schiff theorized that if you suppressed the corpus luteum, you could give the follicular phase more time to develop and may see a more robust ovarian response in the next cycle. That is an interesting alternative hypothesis. The natural response of the hypothalamic-pituitary unit to decreased levels of progesterone is to raise circulating levels of LH and FSH that promote follicular development in the ensuing cycle. In formulating our hypothesis we reasoned that if the hypothalamus were exposed to less progesterone over a shorter period of time, we could find a supraphysiologic acceleration in the LH secretion pattern. In our research experience wherein we induced a supraphysiologic LH secretion pattern we induced luteal phase deficiency. Furthermore, I am not aware of a natural (physiologic) gonadotropin secretion pattern that leads to healthier, more robust follicles. We expected to find either inadequate or normal follicular development in response to luteolysis and we found the latter. It would have been fascinating to have found a more robust subsequent cycle but that was a less plausible hypothesis based on our knowledge of ovarian physiology and our research experience.

Dr. Schreiber asked about a different study design, wherein the effect on the next cycle could be examined after a partially blocking progesterone feedback effect on the hypothalamic-pituitary unit with the progesterone antagonist RU 486. At one time, we considered the use of RU 486 for this purpose but decided against it because we could think of no way to monitor whether we induced a complete or partial block. To mimic luteal phase deficiency only a partial progesterone block at the hypothalamus-pituitary is necessary.

Finally, Dr. Riddick asked whether we have treated women with luteal phase deficiency with progesterone to determine whether the pulse pattern is normal in the subsequent follicular phase. This proposed study is a logical corollary to the study I just presented and we plan to start the very study Dr. Riddick has proposed within the next year.

covering the world

Organons extensive gynaecological product range is esteemed by the medical profession and by innumerable users throughout the world. Similarly, the organisation which develops and supports these products extends world wide. Today Organon includes more than 45 affiliated companies guaranteeing high standards of quality and service.

ORGANON IN GYNAECOLOGY

Assessment of current International Federation of Gynecology and Obstetrics staging of vulvar carcinoma relative to prognostic factors for survival (A Gynecologic Oncology Group Study)

Howard D. Homesley, MD,[a] Brian N. Bundy, PhD,[b] Alexander Sedlis, MD,[c] Edgardo Yordan, MD,[d] Jonathan S. Berek, MD,[e] Antoine Jahshan, MD,[f] and Rodrique Mortel, MD[g]

Winston-Salem, North Carolina, Buffalo and Brooklyn, New York, Chicago, Illinois, Los Angeles, California, and Philadelphia and Hershey, Pennsylvania

Analysis of 588 patients with vulvar carcinoma delineated four risk groups by the proportional hazards model. Groin node status (laterality and number positive) and lesion diameter were the only two important independent prognostic factors. The 5-year relative survival rates were 98%, 87%, 75%, and 29% for the risk group categories of minimal (negative groin nodes and lesion diameter ≤2 cm), low (one positive groin node and lesion diameter ≤2 cm or negative groin nodes and fewer than two lesions ≤8 cm diameter), intermediate (negative groin nodes and lesion diameter >8 cm diameter, one positive groin node and lesion diameter >2 cm, or two unilaterally positive groin nodes and lesion diameter ≤8 cm), and high (three or more positive groin nodes or two bilaterally positive groin nodes), respectively. Applying the International Federation of Gynecology and Obstetrics staging (1988) to these data discriminated risk of death (caused by recurrent vulvar cancer); the 5-year rates were 98%, 85%, 74%, and 31% for stages I, II, III, and IV, respectively. However, within International Federation of Gynecology and Obstetrics stage III there were 47 low-, 95 intermediate-, and 28 high-risk patients with relative survivals of 95%, 74%, and 34%, respectively. Overall, this assessment validates current International Federation of Gynecology and Obstetrics vulvar carcinoma staging, but further refinements are warranted in stage III. (AM J OBSTET GYNECOL 1991;164:997-1004.)

Key words: Prognostic factors, groin node surgical status, tumor size, carcinoma of the vulva, staging

Two prospective clinical trials in vulvar carcinoma, one to evaluate treatment and the other to assess the significance of surgicopathologic staging findings were activated by the Gynecologic Oncology Group in 1977. The prospectively randomized treatment trial of patients with positive groin nodes ended in 1984 and demonstrated that groin plus pelvic radiation therapy was superior to pelvic node resection after radical vulvectomy and groin dissection.[1] From the surgicopathologic study, predictive factors for groin node status in patients with superficial vulvar lesions (tumor thickness ≤5 mm) has been detailed.[2]

Evaluation of the clinicopathologic factors of patients with vulvar carcinoma in the above staging study for prognostic significance for survival are presented. In addition, by classifying the Gynecologic Oncology Group patients into four risk groups for survival, an assessment can be made of the validity of the new surgical staging for vulvar carcinoma formulated by International Federation of Gynecology and Obstetrics (FIGO) in 1988 (Table I).[3]

Material and methods

Only patients with previously untreated squamous cell carcinoma of the vulva, where radical vulvectomy sufficed to resect the primary lesion, were eligible. All patients signed an informed consent form.

6/6/27333

Table I. FIGO staging for vulvar carcinoma (1988)[3]

Stage	*Findings*
I	Tumor ≤2 cm diameter with no nodal metastasis and confined to vulva and/or perineum
II	Tumor >2 cm diameter with no nodal metastasis and confined to vulva and/or perineum
III	Tumor of any diameter with: (1) adjacent spread to lower urethra and/or vagina or anus and/or (2) unilateral regional lymph node metastasis.
IVA	Tumor invasion of any of the following: upper urethra, bladder mucosa, rectal mucosa, pelvic bone, and/or bilateral regional node metastasis
IVB	Any distant metastasis including pelvic lymph nodes

Table II. Frequency and relative survival by groin node status

Node status	*No.*	*%*	*Relative survival at 5 yr (%)*
Negative	385	65.5	90.9
Positive	203	34.5	57.2
TOTAL	588	100.0	
No. positive			
1-2	125	62.5	75.2
3-4	40	20.0	36.1
5-6	19	9.5	24.0
≥7	16	8.0	0.0
TOTAL POSITIVE*	200	100.0	
Laterality			
Unilaterally positive	141	69.5	70.7
Bilaterally positive	62	30.5	25.4
TOTAL POSITIVE	203	100.0	

*Three patients had an undetermined number of positive nodes.

The surgical technique of Parsons and Ulfelder[4] was the standard for all investigators, but individual discretion decided the type of groin incision. Most patients with positive groin nodes were entered into the randomized trial of surgery only versus surgery plus groin and pelvic radiation.

Representative pathology slides were centrally reviewed by the Gynecologic Oncology Group Pathology Committee for uniform pathologic review of location, histologic grade, and number of positive nodes. Evaluation of histologic differentiation of vulvar lesions by Gynecologic Oncology Group criteria, as well as the basis for the most reproducible method for assessment of tumor invasion by measurement of tumor thickness, has previously been presented.[2]

Table III. Frequency and relative survival by node laterality for patients with a unilateral vulvar lesion

Groin node status	*No.*	*%*	*Relative survival at 5 yr (%)*
Negative	201	70.0	91.5
Ipsilaterally positive only	62	21.6	75.0
Contralaterally positive only	8	2.8	26.7
Bilaterally positive	16	5.6	30.5
TOTAL	287	100.0	

Cox's proportional hazards model[5] was used to determine the simultaneous effects of the prognostic factors on survival and relative survival with the likelihood ratio test. A standard step-up procedure identified all independently significant prognostic factors.[6] All medians and life tables were computed with the product-limit estimate by Kaplan and Meier.[7] Survival was defined as the time from study entry to the date of death or date last seen. Relative survival is the time from study entry to date of death or date last seen where deaths from causes other than recurrent vulvar carcinoma were withdrawn alive (censored) in the life-table analysis.

In this article significance refers to statistical significance computed by means of a two-sided statistical test where the p value is ≤ 0.05. Positive nodes, nodal involvement, and nodal spread refer to lymph nodes containing metastases.

The clinical and pathologic factors analyzed for survival were number of positive groin nodes, lesion diameter, surgical margins positive for invasive carcinoma, differentiation of tumor, clinical groin node status, age, lesion location, tumor thickness, and capillary–lymphatic space involvement.

Results

Of 637 patients entered into the study from 1977 to 1984, 49 were deemed ineligible, primarily because of incomplete surgery or inadequate pathologic study, leaving 588 evaluable patients available for analysis.

The surgical extent of metastases in the groin nodes ($p < 0.00001$) was by far the single most important prognostic factor for survival (Table II). Not only was the presence of positive groin nodes associated with a poor prognosis, but the number of positive nodes and whether there was unilateral or bilateral metastases further defined the risk of death. The contribution of the number of positive nodes was powerful. Those with two, four, and six positive nodes experienced 3.1, 6.2, and 11 times the risk of death from cancer compared

Table IV. Frequency and relative survival by tumor diameter and groin node status

	Surgical groin node status					
	Negative nodes			*Postive nodes*		
Tumor diameter (cm)	*No.*	*%*	*Relative survival at 5 yr (%)*	*No.*	*%*	*Relative survival at 5 yr (%)*

2.1-3	120	31.5	90.5	55	27.6	59.1
3.1-4	37	9.7	75.5	44	22.1	56.8
≥4.1	70	18.4	81.5	64	32.2	44.8
TOTAL*	381	100.0		199	100.0	

*Four patients with negative nodes and four patients with positive nodes had unknown lesion diameter.

with the patients with negative nodes, respectively. Bilateral involvement increased the risk by 80% (i.e., relative risk = 1.8). Clinically suspicious or positive nodes (if confirmed to be pathologically positive) increased the risk 50%.

Considering just those patients with unilateral vulvar lesions, contralateral groin metastasis dramatically decreased relative survival (Table III). There were eight (2.8%) patients with contralaterally positive groin nodes and ipsilaterally negative groin nodes.

Multiple regression analysis of relative survival was used to identify the significant independent risk factors. After the number of groin nodes with metastases (the most important risk factor, $p < 0.00001$) was entered into the model, the next most significant ($p = 0.0005$) factor was tumor diameter. Larger diameter tumors were indicative of a lower relative survival and were associated with a greater extent of groin node involvement (Table IV). Comparing small lesions (≤2 cm) with larger lesions (2.1 to 8 cm) yields an improved relative survival between 9 and 18 percentage points for the four categories of extent of groin node involvement (Table V).

The only other independent risk factor was clinical node status ($p = 0.05$). Since the increase in risk associated with clinically suspicious or positive groin nodes was only 60%, it was not useful in discriminating among the four risk groups defined below.

Various other surgicopathologic characteristics were evaluated for survival significance while adjustment for the extent of groin node metastasis and lesion diameter was done. Lesion location, Gynecologic Oncology Group histologic differentiation, standard tumor grading, tumor thickness, status of microscopic resection margins, capillary or lymphatic space involvement, and age were not significant for survival.

A portion of patients was entered on the Gynecologic Oncology Group treatment protocol. The regimens of radiation therapy versus pelvic node dissection, randomly assigned, were evaluated in the model. The beneficial impact of radiation therapy was statistically significant ($p = 0.02$, one-sided test), which is compatible with the published results.[1]

A distinction needs to be made between the factors that can be used to predict nodal status and factors that predict survival (Table VI). Clinical node status, Gynecologic Oncology Group grade, and capillary or lymphatic space involvement were all highly significant ($p < 0.0001$) as predictors of positive groin nodes. Tumor thickness ($p = 0.003$) also was highly prognostic. The odds ratio of increased risk for nodal involvement for age increased fivefold between ages 55 and 65, whereas a 75-year-old woman was 13 times more likely to have positive groin nodes than a 55-year-old woman.

Table VII details the four risk-group assignments with the predicted relative survival on the basis of the two major independent survival determinants of groin node status ($p < 0.00001$) and maximum diameter of the primary tumor ($p = 0.0005$).

The minimal risk group (27%) contains essentially these same patients as currently FIGO stage I. The largest group (40%) of patients are at low risk for recurrence. The low-risk group has lesions either 2.1 to 8 cm in size or ≤2 cm in diameter with only one positive node. The intermediate risk group (18%) is defined by large tumors (>8 cm), larger lesions with a positive node (>2 cm in diameter and one positive node), or two unilaterally positive nodes in a tumor ≤8 cm. The high-risk group (15%) is categorized by large lesions (>8 cm) with two unilaterally positive nodes, three or more positive nodes, or bilaterally positive nodes. Current FIGO staging does not consider a combined higher risk for number of nodes and tumor diameter.

Fig. 1 displays both the relative survival curves of the four Gynecologic Oncology Group risk groups on the basis of this statistical analysis and the 1988 FIGO staging system applied to the same study population. FIGO staging does discriminate relative survival; 5-year rates were 98%, 85%, 74%, and 31% for stages I, II, III, and IV, respectively.

Table V. Relative survival by tumor diameter and surgical groin node status

Tumor diameter (cm)	Negative nodes		No. of positive groin nodes							
			One		Two unilateral		Three or more or two bilateral		Total	
	RS (%)	No.	RS (%)	No.	RS (%)	No.	RS (%)	No.	RS (%)	No.
≤2	97.9	154	94.4	18	88.9	9	38.1	9	94.4	190
2.1-8	86.9	214	76.6	61	70.5	18	28.9	72	73.3	365
>8	65.8	13	66.7	3	50.0	3*	0.0	3	55.7	22

RS, Relative survival at 5 years.

*Last patient in this cell was withdrawn at 14.5 months.

†Three patients had an undetermined number of positive nodes and eight had unknown lesion diameter.

Table VI. Independent risk factors* for groin node metastasis

Factor	p Value
Clinical node status	<0.0001
Gynecologic Oncology Group grade	< .00001
Capillary–lymphatic space involvement	<0.0001
Tumor thickness	0.003
Age	0.04

*These were based on the logistic model.

Of the 176 FIGO stage III patients, the Gynecologic Oncology Group risk designations would be six patients with minimal risk, 47 with low risk, 95 with intermediate risk, and 28 with high risk; relative survivals at 5 years were 100%, 95%, 74%, and 34%, respectively (Fig. 2). This dichotomy is due to differences in definition, specifically FIGO stage III patients with one positive node are considered low risk, whereas those with three or more unilaterally positive groin nodes are high risk with death rates more on par with stage IV patients.

Comment

In 1988 FIGO staging for vulvar carcinoma was revised to include surgical findings. Since a retrospective analysis of a large series of vulvar cancer patients was not available, the current study using the Gynecologic Oncology Group data base, aimed both to delineate the independent survival factors and to assess the validity of the new staging system.

Of all the surgicopathologic findings analyzed that might affect survival, only two factors were found to be independently significant—the extent of disease in the groin nodes and the tumor diameter.

The current study, using the Gynecologic Oncology Group vulvar carcinoma data base, allows extensive scrutiny of the validity of the newly adopted FIGO staging system. Since the new system is a surgically based system that relies heavily on surgical status of the groin lymph nodes, it was no surprise that there was a correlation between stage and survival. Unfortunately, in FIGO stage III the survival ranged between 34% and 100%, depending primarily on the number of positive groin nodes. As emphasized in these current findings, the number of positive nodes is a powerful predictor of outcome and should be included in a vulvar staging system.

Table VII. Gynecologic Oncology Group risk groups for vulvar carcinoma

Risk group*	Surgical findings†	Relative survival at 5 yr (%)	No.‡
Minimal	Tumor ≤2 cm diameter and negative nodes	97.9	154
Low	Tumor 2.1 to 8 cm diameter and negative nodes Tumor ≤2 cm diameter and one positive node	87.4	232
Intermediate	Tumor >8 cm diameter and negative groin nodes Tumor >2 cm diameter and one positive node Tumor ≤8 cm diameter and two unilaterally positive nodes	74.8	104
High	Tumor >8 cm diameter and two unilaterally positive nodes Three or more positive nodes Bilaterally positive nodes	29.0	87

*Evaluation was based on proportional hazards model.

†Findings for nodes were based on surgical pathologic status of groin nodes.

‡Three patients had undetermined number of positive nodes and eight had unknown lesion diameter.

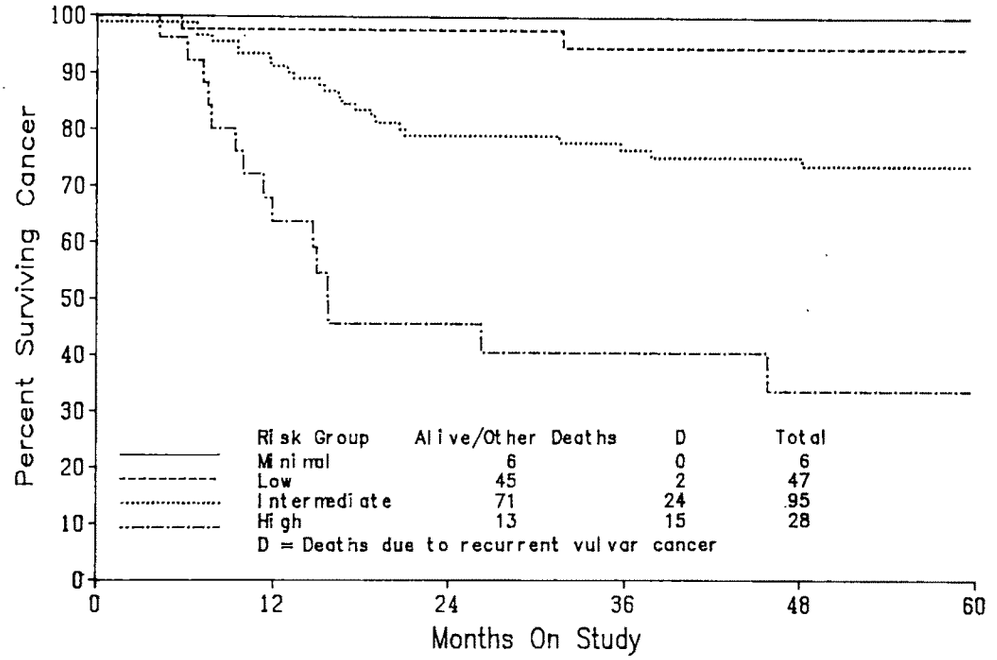

Fig. 1. Relative survival by FIGO stage (1988) versus Gynecologic Oncology Group risk groups, on the basis of the Cox model.

Likewise, the other independent risk factor of increasing diameter of tumor should be specified in a staging system. Lesions up to 8 cm in diameter are low risk as long as groin nodes are negative; however, even patients with negative groin nodes and lesions >8 cm in diameter incur intermediate risk of recurrence.

In combining the two independent risk factors, it is notable that with two unilaterally positive groin nodes (FIGO stage III) and a lesion >8 cm in size the patient is at considerably increased risk for recurrence compared with that of the patient with a lesion ≤8 cm and two positive groin nodes. This study included only three patients with this combination of risk factors. The major fallacy in the current FIGO staging is that there is no consideration in stage III for either increasing lesion diameter or number of positive nodes.

Adjacent spread to the lower urethra, vagina, or anus is categorized as stage III, or high risk, in the new FIGO staging system; yet this disease characteristic was not significant in the regression model ($p = 0.40$). In this study the local site of the lesion did not influence survival. However, this investigation was restricted to those patients with disease deemed resectable by radical vulvectomy and bilateral groin node dissection. This restriction could have eliminated the patients at highest risk of death, such as those with bladder or rectal extension or distant metastasis.

In patients with a unilateral primary lesion (49% of all patients) there was a high relative survival (92%) with negative groin nodes. Survival decreased markedly with ipsilateral groin node involvement (75%) and more drastically with bilateral groin spread (31%). This would justify placement of patients with bilateral regional node metastasis into high risk FIGO stage IVA. Patients with only a contralaterally positive groin node had a low relative survival (27%). However, the contralaterally and bilaterally positive groin node group comprised only 8% of patients with unilateral lesions.

The clinical node status, lesion location, tumor thickness (depth of invasion), Gynecologic Oncology Group differentiation of tumor, standard tumor grade, microscopic resection margins, capillary or lymphatic space involvement, and age in this study had no independent impact on relative survival.

The most powerful prognostic indicator was the number of positive groin lymph nodes. A high relative 5-year survival of 91% is anticipated in negative groin node patients, compared with 75% for patients with one or two positive groin nodes. All of the 16 patients with seven or more positive groin nodes were dead of disease at 5 years. Even the percent of positive groin nodes predicted a poor prognosis when >15% of removed nodes were positive.

The prior Gynecologic Oncology Group report on superficial vulvar lesions dealt primarily with the significance of tumor thickness as it related to depth of invasion and the other predictors of groin node status.[2] Capillary or lymphatic space involvement, Gynecologic

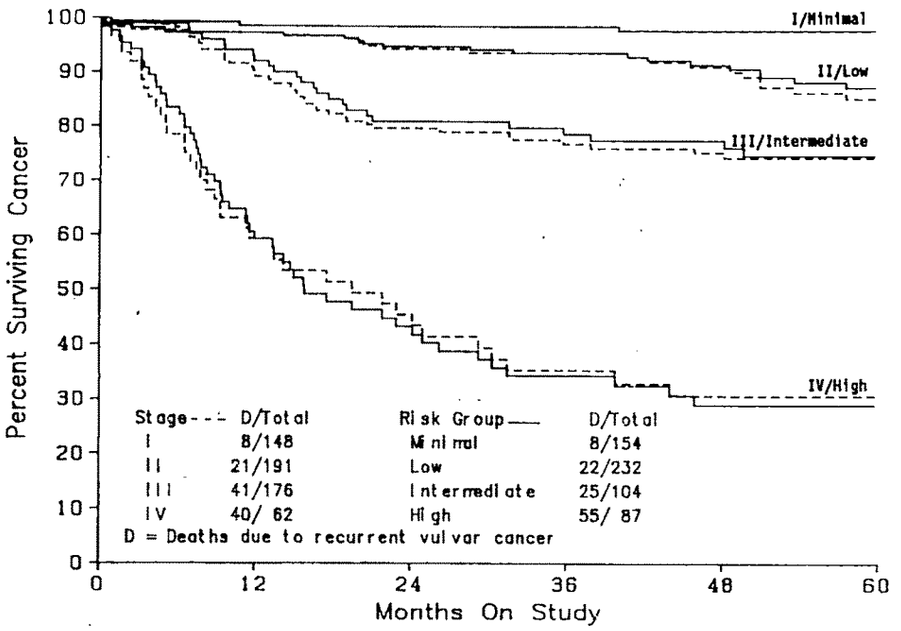

Fig. 2. Relative survival by Gynecologic Oncology Group risk groups, for FIGO stage III patients only.

Oncology Group tumor differentiation, lesion location, and clinical node status, along with tumor thickness, are all predictive of actual groin node status but not survival in patients with superficial lesions.

For this entire data base, in decreasing order, clinical node status, Gynecologic Oncology Group differentiation, capillary or lymphatic space involvement, tumor thickness, and age were the only predictors of groin node status. Nevertheless, only the number of positive groin nodes and tumor diameter are independent prognostic factors for survival that can be precisely used to specify relative risk and are highly predictive of survival.

Overall, the recently revised FIGO vulvar staging system allocates patients into proper risk categories because it is based on surgical staging. Unfortunately there are low-risk patients within stage III with one positive node that may be overtreated, as well as extremely high-risk patients with ≥3 positive nodes who have a poor prognosis.

The four Gynecologic Oncology Group risk groups constructed from the multiple regression analysis can serve as the basis for comparison of any proposed vulvar staging system because it is based on a comprehensive statistical appraisal of a vast number of patients with uniform staging. The two independent factors of groin node status and tumor diameter, when combined, are very powerful in discriminating risk of tumor death. Modifications that are based on Tables V and VII would improve the new vulvar staging system.

Discussion

DR. JOHN ISAACS, Chicago, Illinois. Dr. Homesley and his Gynecologic Oncology Group colleagues have presented a thorough analysis of 588 patients with vulvar cancer. In their initial report they demonstrated in 114 patients that radical vulvectomy, groin dissection, and pelvic radiation gave a better 5-year survival than radical vulvectomy and bilateral groin and pelvic lymph node dissection.

In this presentation the same 114 patients, plus those who have been added since that publication, are being evaluated as to survival on the basis of the 1988 revision of the FIGO staging. The FIGO revision takes into consideration surgicopathologic findings, presumably to give the clinician a better idea of the chances for survival. In the 1988 FIGO staging, however, unilateral lymph node involvement places the patient into stage III regardless of the number of nodes involved. Likewise, if the patient has bilateral groin lymph node involvement, she is categorized into stage IV. Additionally, the FIGO revision does not take into consideration tumor size or diameter.

The authors' concern is that in those patients with stage III disease there is a wide variety of salvage rates, depending on lesion size and the number of positive lymph nodes, whether unilateral or bilateral. It is their opinion that some further refinements of stage III would allow for a more accurate prediction of survival, particularly since some of their stage III patients had a 100% 5-year survival.

It should be pointed out, however, that there is a small subset of stage III breast cancers that have a much better prognosis than most stage III breast malignancies. These are patients with histologically negative axillary nodes and a locally advanced breast cancer. In spite of this known fact, neither the American Joint Committee nor the International Union Against Cancer has suggested a revision of breast cancer staging.

The authors have done an excellent job of analyzing several factors that might influence survival. In so doing they have clearly shown that the number of lymph nodes involved is a powerful indicator of the chances for survival. As the number of positive nodes increases, survival decreases. This seems to apply whether the lymph node involvement is unilateral or bilateral. The other significant prognostic factor noted by the authors was tumor diameter. As the tumor diameter increases, the survival rate drops.

Dr. Homesley states that the statistical analysis eliminated other prognostic factors such as lesion location, degree of differentiation, etc. It is not entirely clear, at least to me, how these factors were eliminated since they did influence the possibility of lymph node involvement.

I would like to ask Dr. Homesley several questions to clarify this excellent presentation. First, do you believe that all 588 cases included in this report followed the precise surgical technique as outlined in the 1968 edition of Parsons and Ulfelder's *Surgical Atlas*? The operation described was quite extensive, and I believe many gynecologic oncologists have modified the dissection considerably since the 1968 edition. The authors stated that only the type of groin incision was left to the discretion of the participating surgeons. If the criteria were not followed precisely, however, alteration in the extent of the surgery could have had an effect on their statistics. One way of determining if the protocol was followed faithfully would be to ascertain if the number of nodes removed in each patient was fairly constant. Do you know the answer to this query?

Secondly, could you expand a bit on how you eliminated the lesion location and histologic differentiation as not being significant for survival? Statistics aside, I would have difficulty believing that a poorly differentiated tumor located in the clitoral area, for example, would not make a difference, nor can I understand that leaving cancer on the surgical margins would have no bearing on the ultimate survival.

Last, how many patients with diseased groin nodes were not entered into the randomized trial of surgery versus surgery plus radiation? In Material and methods it is stated that most patients with positive nodes were entered into the randomized trial of surgery versus surgery plus radiation. Under Results, however, it is stated that only a portion of patients was entered into the Gynecologic Oncology Group treatment protocol. Which was it?

In closing, is further redefinement of the current FIGO staging of vulvar carcinoma really necessary so

soon after its introduction and before further studies have been undertaken?

Dr. William T. Creasman, Charleston, South Carolina. I enjoyed the evaluation very much. I take it that the real concern is stage III, but did I understand correctly that you had eliminated all patients currently in stage III because of adjacent organ location? If that is the case, would that have affected your overall evaluation for stage III?

Dr. Homesley. As Dr. Isaacs may or may not know, all Gynecologic Oncology Group patients who have surgical management are reviewed by a separate committee called the Gynecologic Management Committee. This is a group of gynecologic oncologists who peruse the operative report and sometimes the discharge summaries, as well as look at pathology reports to determine whether the patient met the surgical criteria for entry. This is intense quality control. So I can confirm only that all these cases were carefully reviewed and they met the basic criteria for protocol entry.

As far as the types of groin incisions, morbidity is currently being evaluated. There could be differences in survival between these groups, but here again I think the dominating prognostic feature is the number of positive groin nodes.

No, we did not look for or have any minimum number of nodes for quality control in the groin dissection. We could look at that and determine how many nodes were removed in how many patients and how often the nodes were positive. A statistical evaluation could be done, but I doubt if it would be significant.

There is some confusion about lesion location, and I put this in the manuscript because there is a difference between what is predictive of groin node status and what is prognostic for survival. I think this should be stressed.

There are five predictive factors for groin node status—clinical node status, tumor grade, capillary or lymphatic space involvement, tumor thickness, and age. These are not prognostic factors for survival.

For example, if there is a clinically suspicious node in a patient with a Gynecologic Oncology Group grade 4 tumor that has capillary and lymphatic space involvement in the primary tumor, as well as tumor thickness of 10 or 15 mm, this patient is going to have a worse prognosis because the combination of all these factors is predictive of groin node metastasis from ages 55 to 75 and the relative risk increases 10 or 15 times.

If you're going to do conservative surgery, you have to take all of these predictive factors into account, on the basis of the combined probabilities of the likelihood of groin node metastasis and subsequent prognostic findings. The Gynecologic Oncology Group is conducting a clinical trial that is based on the current findings in which patients with lesions ≤2 cm with negative vascular and lymphatic space involvement and tumor thickness <5 mm are entered into a prospective trial of conservative surgery—hemivulvectomy and ipsilateral groin dissection. Thirteen percent have recurrence of disease and 9% have died. Thus there is a 91% survival with conservative surgery in a restricted group of patients who had favorable clinical and pathologic features.

As for surgical margins, we only dealt with microscopic margins because, as part of the eligibility requirements for the study, the lesions had to be cleared grossly. Even if margins were microscopically positive, it was not frequent enough to affect survival in this large series of patients.

Is it necessary to modify FIGO (1988) vulvar staging? I'm not saying it's necessary to change, but I think before a staging system is altered, it's necessary to take a sizable data base and use statistical methods for computation and prediction of the outcomes. With the large Gynecologic Oncology Group database, I think we can conclude that there will be heterogeneous survivals in stage III patients. If you want to have that, that's fine, but you will be forced to base your prognosis and treatment on the Gynecologic Oncology Group risk groups and not the FIGO staging.

FIGO (1988) vulvar staging is for standardized reporting. It also has some prognostic value, but for treatment I think you may have to use the Gynecologic Oncology Group predictors of groin node status to plan therapy and rely on the Gynecologic Oncology Group risk groups to predict outcome.

Dr. Creasman, I don't really think that there are all that many patients seen in the United States who have adjacent organ spread to justify this as a staging factor. Patients with adjacent site spread (vagina, urethra, and anus) weren't eligible for this study because, at the time we initiated it, it was a clinical pathologic staging of patients who could undergo resection by radical vulvectomy and bilateral groin dissection.

As it turns out, and hopefully not to confuse you, there were six FIGO stage III patients in our population who had lesions ≤2 cm but who had microscopic involvement of the vagina, lower urethra, or anus; all six patients survived. They actually were at minimal risk because they didn't have large lesions or groin node involvement. The two dominant prognostic features for survival are lesion size and number of positive groin nodes, and these two factors should be the basis for a vulvar staging system.

Comparison of pulsatile and continuous ritodrine administration: Effects on uterine contractility and β-adrenergic receptor cascade

Steve N. Caritis, MD, Jye Ping Chiao, MS, and Pam Kridgen, BS
Pittsburgh, Pennsylvania

In this study we compare the uterine contractility and β-adrenergic receptor effects of identical doses of ritodrine administered intermittently or continuously for 24 hours in pregnant sheep. Ritodrine was administered intravenously to five animals as a pulse, 16 μg/kg every 1.5 hours, whereas five other animals received ritodrine as a continuous infusion of 0.18 μg/kg/min. Ritodrine plasma concentrations at steady state were comparable in both groups and averaged 18 ng/ml. Animals receiving ritodrine pulses demonstrated no alteration of myometrial β-adrenergic receptors or adenylyl cyclase activity, and ritodrine inhibited oxytocin-induced contractility comparably at 4 and 24 hours. Animals receiving ritodrine continuously had a significant decrease in myometrial β-adrenergic receptors and adenylyl cyclase activity, yet ritodrine inhibition of oxytocin-induced uterine contractility was sustained for 24 hours. Oxytocin receptors were not affected by ritodrine administration and were similar in both groups. At the dose studied, oxytocin-induced contractions are comparably inhibited by ritodrine for 24 hours whether the drug is given continuously or in a pulsatile fashion. (AM J OBSTET GYNECOL 1991;164:1005-12.)

Key words: Ritodrine, pulsatile, desensitization, down regulation

Berg et al.[1] have demonstrated a reduction in myometrial β_2-adrenergic receptors in pregnant women treated with β_2-adrenergic receptor agonist. These investigators, however, did not evaluate changes in contractility that might occur as a consequence of the reduction in β-adrenergic receptor density. In this regard we have demonstrated that an infusion of ritodrine (1 to 4 μg/kg/min) to pregnant sheep for 24 hours results in a loss of myometrial β_2-adrenergic receptors and a decrease in isoproterenol-stimulated adenylyl cyclase activity in myometrial membranes.[2] These receptor changes are associated with a reduction in the effectiveness of ritodrine inhibition of oxytocin-induced uterine contractility. These findings suggest that the effectiveness of β-adrenergic agonists is self-limited, and indeed clinical studies suggest that the labor-inhibiting effect of β-agonists is short-lived.[3] In many species endogenous substances are released in a pulsatile fashion and the biologic response to the substance is not obtunded with continued exposure of the receptor to its agonist. Ke et al.[4] demonstrated that spontaneous myometrial contractility in vitro could be inhibited for prolonged periods by intermittent exposure to isoproterenol. Continuous exposure to the agonist, on the other hand, led to only transient inhibition of myometrial contractility. We undertook the present study to evaluate the in vivo effect of pulsatile β-agonist administration on myometrial β-adrenergic receptors and inhibition of oxytocin-induced myometrial contractility.

Material and methods

Eighteen sheep at gestational ages of 110 to 125 days (time-dated) were anesthetized with general anesthesia (nitrous oxide/oxygen 1:1 and 0.5% halothane). After laparotomy we obtained two full-thickness uterine biopsy specimens of approximately 1 × 6 × 0.2 cm, weighing 3 to 6 gm. Samples were taken from the ventral surface of the pregnant uterine horn away from the cervix. A catheter was placed in the amniotic cavity and the uterine incision was closed. Polyvinyl catheters were also placed in a maternal pedal artery and vein and in 13 animals in an auricular vein. The arterial catheter was advanced to the abdominal aorta just above the common uterine artery. All catheters were tunneled subcutaneously and stored in a plastic pouch that was sewn to the animal's flank.

Study design. Eight animals were used to determine a pulse frequency and dose of ritodrine that would inhibit oxytocin-induced contractility without significantly reducing myometrial β-adrenergic receptors. We used ritodrine doses of 4 to 16 μg/kg injected every 30 to 120 minutes into the auricular venous catheter. The lowest doses did not provide adequate inhibition,

whereas the highest doses inhibited oxytocin-induced contractions but also caused a loss of myometrial β-adrenergic receptors (data not shown). A dose of 16 μg/kg given every 90 minutes for 24 hours provided adequate inhibition of oxytocin-induced contractility without causing a loss of myometrial β-adrenergic receptors. We therefore used this dosage (256 μg/kg/24 hours) for five animals. For the control group of animals (n = 5) we used the same total dosage (256 μg/kg/24 hours) but administered the drug as a constant infusion. For the 10 study animals we waited 2 to 4 days after surgery before initiating our study. The animals were brought to a study room in a transport cage and were allowed food and water as desired. After a baseline recording of maternal heart rate and uterine activity, all animals received a bolus of 500 mU of oxytocin, which was injected into the femoral artery. Thirty minutes after the oxytocin injection, five animals received ritodrine at a rate of 0.356 μg/kg/min for 30 minutes as a loading dose to rapidly achieve steady-state trough concentrations. This was followed by a maintenance infusion of 0.178 μg/kg/min for 24 hours (total maintenance dose, 256 μg/kg/24 hours). Five animals received three injections of ritodrine, 16 μg/kg every 2 minutes as a pulse through the auricular catheter to rapidly achieve steady-state trough concentrations. This was followed by injections of 16 μg/kg every 90 minutes for 24 hours. The total maintenance dose received in the second group of animals was also 256 μg/kg/24 hours. In the animals receiving ritodrine continuously, we injected 500 mU of oxytocin in the femoral arterial catheter after 4 and 24 hours of ritodrine infusion. In the animals receiving the drug in a pulsatile fashion, 500 mU of oxytocin was injected 60 minutes after the ritodrine pulses, which occurred at 3 and 22.5 hours after ritodrine was started. After 24 hours of ritodrine administration, all animals were killed with a lethal dose of Buthanasia-D (Schering). Myometrial tissue was removed from sites adjacent to the previous biopsy sites and the tissue was prepared as described below.

Tissue preparation. The myometrial tissue used in receptor density or adenylyl cyclase activity assays was frozen immediately in a methanol bath and stored at −70° C. The method for preparing tissue has been previously described.[2] In brief, the myometrial tissue was minced with scissors into 0.2 to 0.5 cm pieces and washed with sucrose buffer (0.25 mol/L sucrose, 1 mmol/L ethylenediaminetetraacetate, and 10 mmol/L Tris hydrochloride at pH 7.4). The tissue was then homogenized with 5 to 10 volumes of sucrose buffer at 4° C with a Brinkman Polytron device at setting No. 7 for 15 seconds, then centrifuged at 3000 g for 10 minutes. The supernatant was centrifuged at 20,000 g for 20 minutes. The pellet was suspended in sucrose buffer and centrifuged again as above. The pellet was resuspended in 0.05 mol/L Tris hydrochloride buffer, pH 7.4, with 0.9% sodium chloride to a final protein concentration of 2 to 3 mg/ml. Aliquots of myometrial membranes were then quickly frozen in a methanol bath and stored at −70° C until assayed within 60 days.

Measurement of β-adrenergic receptors, oxytocin receptors, and adenylyl cyclase activity

β-Adrenergic receptor assay. Myometrial membranes were thawed at room temperature and assayed for protein content by the method of Lowry et al.[5] Membranes (100 to 200 μg) in 0.05 mol/L Tris hydrochloride buffer were incubated in duplicate with 0.5 to 3.0 nmol/L [^{3}H]dihydroalprenolol (New England Nuclear) in a volume of 250 μl for 20 minutes at 30° C. Binding was at equilibrium under these conditions.[2] Nonspecific binding was determined with 10 μmol/L l-propranolol. Incubations were terminated by adding 3 ml of ice-cold Tris buffer that was quickly filtered through Whatman GF-C filters. The filters were washed with 5 ml of ice-cold Tris buffer three times, dried in an oven, placed in scintillation vials containing 5 ml of scintillation cocktail, and counted to 5 minutes by a Packard Tri-Carb scintillation counter (efficiency = 70%).

Oxytocin receptor assay. We used the method of Riemer et al.[6] to measure myometrial membrane oxytocin receptor density. We incubated 100 μg of membrane protein with 0.4 to 8.0 nmol/L [^{3}H]oxytocin (Sigma). Nonspecific binding (<20%) was determined from binding of [^{3}H]oxytocin to membranes in the presence of 1 μmol/L oxytocin.

Adenylyl cyclase activity. We used the competitive protein-binding method of Gilman[7] to measure the conversion of adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP).[10] Membrane protein (20 to 40 μg) was incubated in duplicate for 15 minutes at 37° C with 50 mmol/L HEPES buffer, pH 7.4, 8 mmol/L potassium chloride, 1 mmol/L isobutyl methylxanthine, 3 mmol/L dithiothreitol, 0.4 mg/ml bovine serum albumin, 6 mmol/L magnesium chloride, 1 mmol/L of ATP, 0.25 mmol/L creatine phosphate, and 0.075 mg/ml creatine phosphokinase to a final volume of 300 μl. Reactions were terminated by adding 75 μl of 150 mmol/L acetic acid at room temperature. The membranes were centrifuged at 3000 g for 15 minutes. An aliquot of the supernatant containing cAMP was incubated with 5 to 10 μg cAMP-binding protein kinase and 0.05 μCi of [^{3}H]cAMP (New England Nuclear). Binding reached equilibrium by 2 hours; therefore all incubations were performed at 4° C for 2 hours. One milliliter of charcoal solution was added to each tube, which was centrifuged at 3000 g for 10 minutes. The supernatant was counted in a Packard Tri-Carb liquid scintillation counter after addition

of scintillation cocktail. We quantified cAMP by comparing the unknown samples with cAMP standards (1 to 24 pmol) prepared with the same reagents. Each microgram of cAMP-dependent protein kinase from bovine heart binds 0.12 pmol of cAMP at 40 nmol/L, pH 4 at 0° C. Others have found that cross-reactivities with other cyclic nucleotides are <1% that of cAMP.[7] The relationship of membrane protein concentration to cAMP production was linear (n = 0.996) from 2.8 to 57 μg protein. Interassay and intraassay variability was 13%. Basal adenylyl cyclase activity was not increased by isoproterenol without the presence of guanyl nucleotides. We therefore added 10 μmol/L 5'-guanylylimidodiphosphate to all incubations with isoproterenol. We also added 10 mmol/L sodium fluoride to some incubations without isoproterenol or guanyl nucleotides to evaluate postreceptor adenylyl cyclase activity.

Quantification of uterine activity. Uterine activity was measured by a Statham pressure transducer and recorded on a multichannel recorder. Uterine activity was quantified by integrating the area under the time–uterine pressure curve with the Bioquant II program (R & M Biometrics). We compared the area under the curve for a 10-minute epoch before oxytocin injection and again for 10 minutes after oxytocin injection. For the animals receiving ritodrine as a pulse, baseline uterine activity was recorded between 50 and 60 minutes after the ritodrine pulse. Oxytocin was injected at 60 minutes, and the uterine response was recorded from 60 to 70 minutes after the ritodrine pulse.

We have previously shown that in sham-operated animals receiving oxytocin pulses intermittently during a 24-hour infusion of saline solution there were no changes in β-adrenergic receptor density or adenylyl cyclase activity. Repeated pulses of oxytocin produced a reproducible myometrial response.[2]

Ritodrine measurement. Blood (10 ml) was collected in heparinized syringes before ritodrine infusion and during the ritodrine infusion preceding each injection of oxytocin. In animals receiving ritodrine in a pulsatile fashion, blood was also obtained at 45, 60, 65, and 70 minutes after ritodrine injection. Thus in the latter group four blood samples were obtained during the 25-minute epoch in which baseline activity was recorded and the uterine response to oxytocin was quantified. Samples were centrifuged at 1500 g for 10 minutes, and the supernatant plasma was frozen at −20° C until analyzed by high-performance liquid chromatography with μBondapak C_{18} reverse-phase column and electrochemical detection.

Statistical analysis. Changes in β-adrenergic receptor density, adenylyl cyclase activity, and area under the uterine pressure–time curve in the two groups were compared by two-way analysis of variance and the Newman-Keuls test. Time and treatment regimen were used as the two grouping factors for the two-way analysis of variance. All values are expressed as mean ± SD except in Fig. 1, where data are mean ± SE.

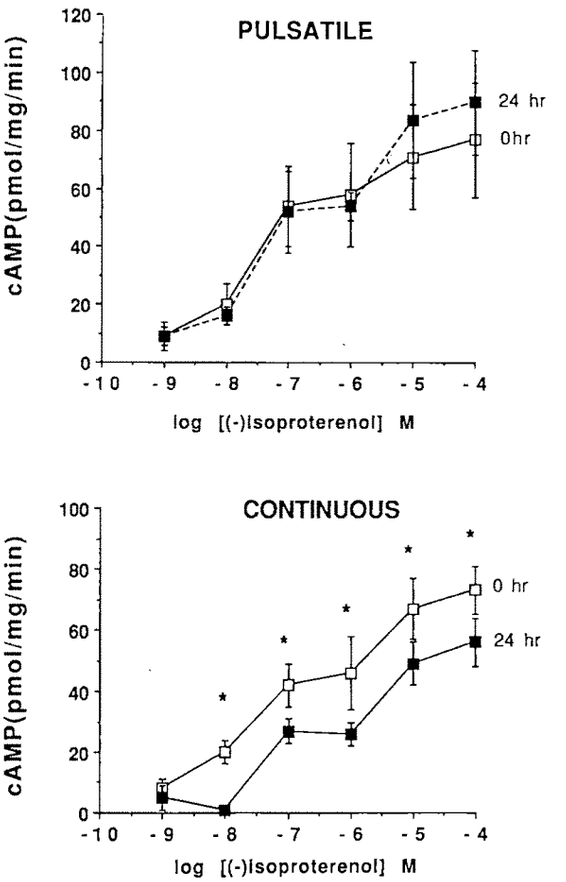

Fig. 1. Adenylyl cyclase activity in ovine myometrial membranes from animals receiving ritodrine by pulsatile *(top)* or continuous *(bottom)* infusion. Membranes obtained before ritodrine administration and after 24-hour ritodrine infusion were incubated with various concentrations of *l*-isoproterenol. Amount of cAMP produced is directly related to amount of adenylyl cyclase activity. *Asterisks* indicate significantly different values between 0 and 24 hours.

Results

The changes in myometrial β_2-adrenergic receptor quantity, agonist affinity (dissociation constant), and area under the uterine pressure–time curve in the two groups of animals are summarized in Table I. In animals receiving ritodrine in a pulsatile fashion no significant change in myometrial β-adrenergic receptor density or agonist affinity was demonstrated. Uterine response to oxytocin was reduced by 40% ($p < 0.05$). This degree of inhibition was maintained for the duration of ritodrine administration.

Animals receiving ritodrine continuously had a 42%

Table I. Uterine effects of ritodrine during pulsatile and continuous administration

	Pulsatile ($n = 5$)	*Continuous* ($n = 5$)

0 hr	15 ± 3	22 ± 7
4 hr	9 ± 2*	11 ± 5*
24 hr	9 ± 2*	12 ± 7*

*$p < 0.05$.

decrease in myometrial β-adrenergic receptors ($p < 0.05$) but no change in the dissociation constant. Oxytocin-induced contractility at 4 hours was inhibited by 50% ($p < 0.05$). In spite of the changes in β-adrenergic receptor density, the ability of ritodrine to inhibit oxytocin-induced contractility was not reduced after 24 hours of the infusion.

Fig. 1 shows the activation of adenylyl cyclase by various concentrations of *l*-isoproterenol. At concentrations >10 nmol/L, the adenylyl cyclase activity of myometrial membranes from animals receiving ritodrine continuously was significantly less than that of tissue from animals receiving the drug in a pulsatile fashion ($p < 0.05$). At a concentration of 0.1 mmol/L, adenylyl cyclase activity was 26% lower in animals receiving ritodrine continuously than in animals receiving ritodrine in a pulsatile fashion. Table II shows that basal adenylyl cyclase activity, sodium fluoride–stimulated adenylyl cyclase activity, and mean effective concentration of isoproterenol did not change significantly in either group as a consequence of ritodrine administration. Similarly, as indicated in Table III, oxytocin receptor density and dissociation constant were not altered by either regimen of ritodrine administration.

In animals receiving ritodrine at a constant rate, the concentrations at 4 and 24 hours were 15 ± 4 and 18 ± 5 μg/ml, respectively. Thus steady state had essentially been achieved by the fourth hour of infusion. In the animals receiving ritodrine pulses, the ritodrine concentration was measured four times between 45 and 70 minutes after a ritodrine pulse and averaged 14 ± 2 and 18 ± 3 μg/ml at 4 and 23.5 hours, respectively. These concentrations were similar to those seen with the continuous infusion protocol. There was little variation in the ritodrine concentration between the 45- and 70-minute time points. In the five animals the mean variation in ritodrine concentration at these two time points was 0.9 ± 2.0 ng/ml. Thus the ritodrine concentrations were relatively constant during oxytocin-induced uterine contractility.

Comment

This study has demonstrated that the pulsatile administration of ritodrine at the dose and frequency described does not significantly reduce myometrial β-adrenergic receptor density or adenylyl cyclase activity. Ritodrine inhibition of oxytocin-induced contractility is maintained for 24 hours. Continuous infusion of the same dose of ritodrine for 24 hours, however, results in a 42% loss of β-adrenergic receptors and a 26% reduction in isoproterenol-stimulated (0.1 mmol/L) adenylyl cyclase activity. Despite these receptor-mediated changes during continuous ritodrine infusion, there was no attenuation of ritodrine's ability to inhibit oxytocin induced contractility after 24 hours' infusion.

Our previous work has shown that the continuous infusion of high doses of ritodrine for 24 hours results in a reduction of myometrial β-adrenergic receptors, a loss of isoproterenol-stimulated adenylyl cyclase activity, and an attenuation of ritodrine inhibition of oxytocin-induced contractions.[2] These receptor effects were observed with plasma concentrations ranging from 45 to 164 ng/ml. In this study we demonstrated similar effects on β-adrenergic receptor density and isoproterenol-stimulated adenylyl cyclase activity with ritodrine concentrations averaging 18 ng/ml (range, 10 to 25 ng/ml). The lowest concentration of ritodrine required to reduce β-adrenergic receptor density and adenylyl cyclase activity has not been established. β-Adrenergic receptor loss in this study occurred at concentrations that minimally stimulate adenylyl cyclase activity, i.e., 30 ng/ml (unpublished data).

In spite of qualitatively similar effects of continuous ritodrine infusion on the β-adrenergic receptor and isoproterenol-stimulated adenylyl cyclase activity, the inhibitory effect of ritodrine on oxytocin-induced uterine contractions differed between this study and our previous study. In contrast to the previous study, the receptor effects described here were not accompanied by an attenuation of ritodrine inhibition of oxytocin contractility in this study. The reason for this differ-

ence is unclear. One possible explanation may be the quantitative differences in receptor effects between the two studies. Both the magnitude of the receptor loss (50% vs 42%) and the adenylyl cyclase response to 0.1 mmol/L isoproterenol (70% vs 26%) were greater in the previous study. Plasma ritodrine concentrations averaged 85 ng/ml in the previous study and only 18 ng/ml in this study. Quantitative comparisons between the two studies, however, are problematic. The number of animals in the two studies was small and substantial variation exists in receptor-associated effects between animals. Another possible explanation for the different uterine response is that the higher ritodrine concentrations in the previous study altered the hormonal milieu in such a fashion to make the myometrium more responsive to oxytocin. We measured oxytocin receptor density and agonist affinity in the present study, these were unaffected by ritodrine infusion. We did not, however, measure oxytocin receptors in our previous study. Additionally, ritodrine increases uterine production of prostaglandins.[8] This effect may be dose related and may account for the greater uterine responsiveness to oxytocin in our previous study. It is also possible that during continuous infusion of ritodrine, numerous intracellular processes that may be responsible for the process of desensitization may be affected to a greater degree with higher doses of ritodrine. For example, phosphodiesterase activity may be increased to a greater degree with higher ritodrine concentrations, resulting in more rapid degradation of cAMP.[9]

The decrease in β-adrenergic receptors after continuous ritodrine infusion was associated with a similar but somewhat smaller decrease in membrane adenylyl cyclase activity. This finding suggests that there are few "spare receptors" in ovine myometrium. The concept of spare receptors was developed to explain how adenylyl cyclase activity is maintained in many tissues despite a substantial decrease in β-adrenergic receptors.[10] This clearly was not the case in this study. The observation that adenylyl cyclase activity decreased by 26% while receptor decreased 42% suggests that the pool of spare receptors is small.

The dose-response studies with isoproterenol indicate an attenuation of response at all concentrations >10 nmol/L isoproterenol in animals receiving ritodrine continuously. Basal adenylyl cyclase activity, as well as fluoride-stimulated activity, was not affected, indicating that the reduced adenylyl cyclase response is not mediated through a decreased amount of adenylyl cyclase enzyme. Fluoride ion stimulates adenylyl cyclase, directly bypassing the receptor mechanism. A robust adenylyl cyclase response to sodium fluoride indicates that adenylyl cyclase itself is not affected by continuous ritodrine infusion.

Ke et al.[4] have shown that spontaneous myometrial contractility in vitro can be inhibited for prolonged periods with intermittent, but not continuous, exposure to β-agonists. Casper and Lye[11] administered ritodrine and isoproterenol to nonpregnant oophorectomized sheep and measured estradiol-induced uterine contractility. A continuous infusion of a β-agonist initially inhibited uterine contractility but the effect was short-

lived, lasting 6 to 10 hours. Intermittently administered isoproterenol (30 minutes on and 30 minutes off) inhibited uterine contractility for 13 hours. The greatest degree of inhibition occurred during the isoproterenol infusion; uterine contractility increased substantially during the 30-minute period that the infusion was stopped. In the study of Casper and Lye,[11] several regimens of intermittent ritodrine administration were not successful in maintaining uterine quiescence for long periods. Our success with ritodrine is likely attributable to the integration of pharmacokinetic and pharmacodynamic data specific to ritodrine. We selected a dose and pulse frequency that would keep trough plasma concentrations of ritodrine at <30 ng/ml. We have found that ritodrine stimulation of adenylyl cyclase activity is minimal at concentrations <100 nmol/L, i.e., 30 ng/ml (unpublished data). We supposed that receptor-mediated effects might be minimized if there were insufficient binding of ritodrine to β-adrenergic receptors to stimulate cyclase activity.

We were surprised to find that plasma ritodrine concentrations were similar in the two groups of animals. Theoretically, with the dosing regimens used in the study, trough ritodrine concentrations would be expected to be lower than the steady-state concentrations during a constant infusion of the same dosage. Ritodrine plasma concentration is dependent on drug clearance. Ritodrine clearance, however, can vary as much as threefold.[12] Since our study was cross-sectional, the similarity in ritodrine concentrations in the two groups is probably due to interanimal variation in ritodrine clearance. Had each animal received ritodrine by both regimens, we would have expected to demonstrate a somewhat lower trough plasma concentration in animals receiving the drug as a pulse. Such a study design, however, would have prevented an analysis of the myometrial receptor effects.

In many tissues of various species, continuous exposure of β-adrenergic receptors to β-agonists leads to a reduction in receptor number.[10] The agonist-receptor complex is phosphorylated and may be internalized, making it inaccessible to further agonist binding. It is unclear why receptors were not lost in those animals receiving the drug in a pulsatile fashion. Plasma concentrations at steady state were not significantly different in the two groups, suggesting that the different receptor effects in the two groups were not attributable to differences in plasma ritodrine concentrations. Plasma progesterone concentrations were not significantly altered by either drug administration regimen (data not shown). Therefore the different effect on β-adrenergic receptor density cannot be explained by differential effects of ritodrine on progesterone release or production. One possible explanation for these differential receptor effects is that the transiently high ritodrine concentration after a pulsatile injection inhibits the phosphorylation of the receptor, preventing its sequestration. Alternately, transiently high ritodrine concentrations may enhance transcription of new receptors.

The clinical implications of this study are numerous. It is clear that a loss of β-adrenergic receptor density does not mean that the clinical effectiveness of a β-agonist is lost. In view of the low ritodrine concentration required to reduce β-adrenergic receptors, it is likely that even with the lowest dose of ritodrine used to treat preterm labor, a marked loss of β-adrenergic receptors will occur.[13] Recently β-adrenergic receptor density in peripheral lympocytes in humans has been closely correlated with myometrial β-adrenergic receptor density.[14] Our findings suggest, however, that a reduction in receptors in either tissue does not necessarily mean a loss of tocolytic effectiveness.

Recently the β-agonist terbutaline has been administered in a pulsatile fashion to pregnant women to prevent recurrent preterm labor.[15] The dosing frequency and quantity were titrated to spontaneous uterine contractility and were not based on the pharmacokinetic properties of the β-agonist. There is no evidence that the recommended regimen prevents receptor loss or maintains tocolytic efficacy. Our preliminary studies in this report indicate that too frequent or too high a dose will cause a loss of receptors and a loss of tocolytic efficacy. Clearly, additional studies are required to define the dose response for β-adrenergic receptor loss, the decrease in adenylyl cyclase activity, and the loss of tocolytic effectiveness after pulsatile β-agonist administration.

Discussion

DR. ROBERT C. CEFALO, Chapel Hill, North Carolina. In the United States, preterm labor and delivery still account for the majority of the neonatal morbidity and mortality, in spite of the implementation of preterm labor prevention protocols and the use of different classes of tocolytic agents. It appears that both the failure rate and side effects of certain tocolytic agents are related to the β-receptor/β-agonist interaction. During therapy with β-agonist drugs, recurrent preterm labor is believed to be secondary to a down regulation or desensitization of the myometrial β_2-adrenergic receptors, which leads to a state refractory to further tocolysis. Clinically, the limited duration of relaxant effect of β_2-adrenergic receptor agonist as a treatment of preterm labor makes this a relevant and important question. Caritis et al. attempted to clarify the mechanism behind the desensitization of the myometrial β_2-adrenergic receptor after exposure to a β_2-adrenergic receptor agonist. Desensitization of the β-adrenergic receptor system may come about by a decrease in the number of receptors or a decrease in the total adenylate cyclase activity. These desensitization mechanisms have been demonstrated in vitro and clinically after continuous exposure of adrenergic receptor stimulation. This phenomenon has led investigators and clinicians to consider the use of a pulsatile bolus of a β-agonist in an attempt to overcome the desensitization associated with continuous infusion.

The authors investigated and compared the in vivo effect of continuous β-agonist and pulsatile β-agonist administration on myometrial β-adrenergic receptor activity and inhibition of oxytocin-induced myometrial contractility in a near-term pregnant sheep model. Their findings indicate that the animals receiving ritodrine pulses demonstrated no alteration of myometrial β-adrenergic receptor activity, and ritodrine inhibited oxytocin-induced contractility comparably at 4 and 24 hours. The animals receiving ritodrine continuously had a statistically significant decrease in myometrial β-adrenergic receptor activity, yet the ritodrine inhibition of oxytocin-induced uterine contractility was sustained for 24 hours. Neither pulsed nor continuous administration of ritodrine affected oxytocin receptors. Thus, after rigorous scientific investigation that involved the pharmacokinetics of the β-agonist, sophisticated quantification of β-adrenergic receptor, oxytocin receptor, and adenylyl cyclase activity, we are left with more knowledge but further questions.

Stimulation and increase in density of β-adrenergic receptors in both pregnant and nonpregnant human or animal myometrium by β-adrenergic receptor agonists results in smooth muscle relaxation. This up regulation of β-adrenergic receptor and adenylate cyclase function may be regulated in part by local or systemic estrogen-progesterone levels.[1] In many species it is known that both local and systemic placental progesterone production are important for pregnancy maintenance and uterine relaxation. In pregnancy, local progesterone secretion results in functional adrenergic denervation of the myometrium, which may contribute to the observed up regulation of the β-adrenergic receptor function and increase in the number of β-adrenergic receptors and in adenylate cyclase activity contributing to myometrial relaxation and pregnancy maintenance.

In the pregnant ewe an extremely high plasma progesterone concentration is maintained until delivery. The concentration of estrogens in maternal plasma is low during most of the pregnancy and increases tenfold on the day before labor. Just before the onset of labor there is an alteration in the estrogen-to-progesterone ratio that may be involved in the sensitivity of the myometrium to the effects of oxytocin and prostaglandins.

I have three questions for Dr. Caritis. Is progesterone production affected by either pulsatile or continuous ritodrine administration? In view of the known progesterone and estrogen effects on β-adrenergic receptor activity, did the authors take into account that the quantification of myometrial adrenergic receptor and adenylate cyclase activity may have been affected by relative levels of estrogen and progesterone in the maternal circulation as well as locally, whether the myometrial biopsy specimen was taken over the cotyledonary site or between cotyledons? By the methods used, could the authors differentiate between the uterine smooth muscle membrane fraction and the smooth muscle membrane fraction from small-caliber blood vessels obtained in their myometrial biopsy specimens?

The authors are to be congratulated for attempting to further clarify β-adrenergic receptor mechanisms and classify the range of responses to β-agonist administration, looking for the lowest possible dose compatible with a clinical effect. It is only through a basic

understanding of these mechanisms that we can come closer to suggesting a therapeutic approach that can assist in the management of preterm labor.

DR. THOMAS H. KIRSCHBAUM, Los Angeles, California. Dr. Caritis, I wonder if we aren't looking at the wrong source of intracellular energetics in this case. As I remember, there is some evidence in the human and in some animals that the conversion of ATP to cAMP is less important quantitatively than the activity of inositol triphosphate in driving calcium metabolism inside cells: Am I correct? Is this a possible explanation?

DR. CARITIS. First, I would like to respond to Dr. Cefalo's questions, whether progesterone production is affected by the administration of ritodrine and, if so, is there a difference between a pulsatile and continuous infusion. We measured progesterone but have not yet measured estrogen concentrations in these animals. There was no effect of either regimen on plasma progesterone concentrations.

Furthermore, steady-state concentrations were similar in the two groups. Thus, if there was an effect of ritodrine on the progesterone concentrations or β-adrenergic receptor density, the effect would have been comparable in the two groups.

In response to the question about biopsy site, our biopsies were always done between cotyledons. A biopsy over the cotyledonary site would lead to fairly heavy bleeding so we tried to avoid performing biopsies near cotyledons.

In the previous study, where we validated our animal model, we obtained myometrial biopsy specimens from various regions to determine the regional variation of β-adrenergic receptor density. We found, on average, about a 22% regional variation. Most of the variation occurred when we compared receptor density from tissue close to the cervix to tissue distant from the cervix. To minimize the regional variation in receptor density, we obtained two biopsy specimens at each time point.

Dr. Cefalo asked if there is some way we could separate vascular and uterine smooth muscle β-adrenergic receptors. When we obtained our myometrial tissue, we scraped the tissue with a glass slide to remove decidua and the large blood vessels. Smaller blood vessels and capillaries, however, were not removed.

It is assumed that the contribution to the total β-adrenergic receptor density by vascular β-adrenergic receptors is small. Further, since each animal serves as its own control, the contribution of vascular β-adrenergic receptors to the entire receptor pool would be constant.

I'm afraid I can't answer Dr. Kirschbaum's question. There is ample evidence that cAMP is not the only regulator of smooth muscle contractility. Some of our own data do not quite fit a model that relies totally on cAMP as the overall determinant of uterine contractility.

Rapid intramembranous absorption into the fetal circulation of arginine vasopressin injected intraamniotically

William M. Gilbert, MD, Cecilia Y. Cheung, PhD, and Robert A. Brace, PhD
San Diego, California

Recently an intramembranous pathway was reported in the ovine fetus as a route for the movement of a significant volume of water from the amniotic cavity directly into the fetal blood, which perfuses the fetal membranes and fetal surface of the placenta. To test whether this pathway could be an avenue for the movement of arginine vasopressin from the amniotic cavity into the fetal circulation, we injected 1 to 25 μg of arginine vasopressin into the amniotic cavity of two groups of chronically catheterized fetal sheep: a control group of seven animals and a group of seven animals with surgical ligation of the fetal esophagus. We found similar and highly significant increases of arginine vasopressin concentrations in both control and surgically ligated fetuses in amniotic fluid ($p < 0.00001$), fetal plasma ($p < 0.0001$), and fetal urine ($p < 0.0001$). Both groups had similar increases in arterial ($p < 0.0001$) and venous ($p < 0.003$) pressures with simultaneous decreases in urine flow ($p < 0.001$) and heart rate ($p < 0.0001$) after the intraamniotic injection of arginine vasopressin. We conclude that amniotic arginine vasopressin can be rapidly absorbed in its biologically active form directly into the fetal circulation through the intramembranous pathway. Furthermore, the observation that esophageal ligation did not alter this absorption suggests that the intramembranous pathway may be important in the regulation of amniotic fluid volume and composition. (Am J Obstet Gynecol 1991;164:1013-20.)

Key words: Vasopressin, amniotic fluid, intramembranous pathway

The intramembranous pathway for the movement of water from the amniotic cavity directly into the fetal blood, which perfuses the fetal membranes and fetal surface of the placenta, has been described in pregnant sheep.[1] In our previous study, we found that warmed distilled water injected into the amniotic cavity was rapidly absorbed into the fetal circulation, resulting in highly significant decreases in plasma osmolalities and electrolyte concentrations. Furthermore, this absorption of amniotic water occurred more rapidly in a group of fetuses with ligated esophagi. These observations clearly showed that not only can significant volumes of amniotic water be absorbed through the intramembranous pathway into the fetal circulation under normal physiologic conditions, but also that ligation of the fetal esophagus resulted in an increase in conductance of the intramembranous pathway. This raises the possibility that the intramembranous pathway may play a primary role in the determination of both the volume and the composition of the amniotic fluid.

Arginine vasopressin is normally present in fetal plasma and amniotic fluid. Arginine vasopressin is a low molecular weight (1084 daltons) vasoactive substance that has significant cardiovascular and renal effects in the fetus. Arginine vasopressin is present early in gestation and is known to increase acutely during periods of fetal stress including hypoxia and hemorrhage.[2-4] Infusions of arginine vasopressin into the fetal circulation resulted in a dose-dependent increase in arterial and venous pressures and decreases in urine output and heart rate.[5, 6]

Arginine vasopressin is found in amniotic fluid at levels comparable to those in fetal plasma and the question arises as to what overall role arginine vasopressin may play in amniotic fluid volume regulation. Amniotic fluid arginine vasopressin may act as a reservoir for fetal plasma arginine vasopressin because injections of arginine vasopressin into the amniotic cavity resulted in sustained high amniotic levels for 24 hours or longer.[7] Previously, Ervin et al.[8] injected 25 μg of arginine vasopressin into the amniotic cavity of fetal sheep to examine the recirculation of arginine vasopressin from the amniotic fluid into the fetus. Their study showed significant increases in fetal plasma arginine vasopressin concentrations within 30 minutes after the injection without significant changes in fetal blood pressure or heart rate. They concluded that arginine vasopressin was absorbed by fetal swallowing.

To determine whether the intramembranous pathway can provide a means for recirculation of amniotic

fluid arginine vasopressin in addition to fetal swallowing, this study was designed to examine whether this pathway could play a role in the movement of arginine vasopressin from the amniotic cavity into the fetal circulation in intact and esophageal-ligated fetuses.

Methods

The protocol for this experiment was approved by the animal use committee in our university and we followed the National Institutes of Health guidelines for the use and care of laboratory animals. Fourteen time-dated pregnant sheep (Nebeker Ranch, Lancaster, Calif.) at a mean (±SEM) of 128 ± 1 days' gestation at the time of surgery were used for this study. The surgical procedures, briefly described here, are detailed elsewhere.[9] The animals were anesthetized with 1 gm of thiamylal sodium given intravenously, and maintained with halothane (0.5% to 2%) in oxygen. In the supine position, using aseptic techniques, a midline incision was made in the abdominal wall and the uterus was exposed through the abdominal incision. The fetal hind limbs were brought out of a uterine incision and bilateral anterior pedal arterial and saphenous venous catheters were placed and advanced to the level of the diaphragm. A suprapubic bladder catheter was placed through a lower abdominal incision. Amniotic fluid catheters were tied to each hind leg and bladder catheter incision site. The fetus was returned to the uterus and fetal membranes were ligated around the catheters twice to prevent leakage of amniotic fluid. The uterus was closed in a watertight manner with a continuous suture. In seven of the animals a second uterine incision was made over the fetal neck and the esophagus was identified and ligated twice. The incision in the neck was closed as was the uterine incision in a similar watertight manner as described in this article. Maternal femoral arterial and venous catheters were placed and advanced to the level of the maternal diaphragm. All catheters were tunneled subcutaneously into a pouch sewn on the flank of the ewe.

The vascular catheters were flushed daily with heparin sodium (1000 U/ml). Antibiotics (1 gm ampicillin, Omnipen, Wyeth Laboratories, Philadelphia) were given daily into the amniotic cavity and intramuscularly (800,000 U of penicillin and 1 gm dihydrostreptomycin) to the ewe during the postoperative period.

Experiments were begun 5 days after surgery. The fetuses were monitored continuously for arterial and venous pressure levels, amniotic fluid pressure, urine flow rate, and heart rate. After a 30-minute control period, a bolus of arginine vasopressin (1 to 25 μg) was injected into the amniotic cavity of seven control fetuses and seven esophageal-ligated fetuses. Immediately after injection of the arginine vasopressin, the amniotic fluid was mixed by repeated withdrawal and reinjection of 60 ml of amniotic fluid. Fetal and maternal plasma, amniotic fluid, and fetal urine were sampled at 10 and 20 minutes during the 30-minute control period, and at 10, 20, 30, 45, 60, and 120 minutes after the injection of arginine vasopressin. Fetal arterial blood was sampled for blood gas and pH values (model 1302 blood gas analyzer; Instrumentation Laboratory, Lexington, Mass.), sodium, chloride, and potassium ion concentrations (Nova model 5 + 5 electrolyte analyzer), osmolality (freezing-point depression, Advanced Instruments Inc., Needham Heights, Mass.), hematocrit, and plasma concentration of arginine vasopressin. Maternal blood, amniotic fluid, and fetal urine were sampled for electrolytes, osmolality, and plasma arginine vasopressin concentration at the same times as above. Fetal urine was collected from the bladder catheter, which first went through a computer-controlled roller pump. There was approximately 5 ml of catheter dead space between the bladder and sampling port. With a basal urine flow rate of 0.4 ml/min, urine samples were obtained with a 15-minute delay relative to the respective plasma and amniotic samples. Fetal urinary bladder catheters were functioning in six control animals and five surgically ligated animals at the time of experimentation.

Radioimmunoassay. Plasma, urine, and amniotic samples were extracted with C18 microcolumns (Sep-Pak, Waters Associates, Milford, Mass.) and arginine vasopressin concentrations were measured by radioimmunoassay with an antiserum generously provided by Dr. Ben U (University of California, San Diego) and tracer obtained from New England Nuclear (Boston) as previously described.[10] Extraction recovery averaged 84 ± 3% and sensitivity was 0.2 pg/tube. The intraassay and interassay coefficients of variation were 5.6% and 16%, respectively.

Statistical analyses. The data are presented as the mean ± SE. Changes with time in a single variable were analyzed with a two-factor analysis of variance with time and animal being the two factors. All arginine vasopressin concentrations (urine, plasma, and amniotic fluid samples) were log transformed before analysis to correct for skewness of data. To determine whether changes in time in one variable were significantly different in the two groups of animals, a three-factor analysis of variance was used with time, treatment, and animal being the factors. Statistical significance was accepted at $p \leq 0.05$ and changes referred to as significant are at this level unless specified otherwise.

At the end of the experiment, the animal was killed with sodium pentobarbital (300 mg/kg), an autopsy was performed on the fetus, and fetal weight was recorded.

Results

Mean values during the control period for the two groups of animals are shown in Table I and are not different from those values found previously in our

Table I. Mean (±SE) control values

	Control	*Ligated esophagus*
Fetus		
Gestational age (days)*	133 ± 1	132 ± 1
Urine flow rate (ml/min)†	0.47 ± 0.08	0.34 ± 0.01

Data from seven control and seven surgically ligated fetuses.

*Gestational age at start of experiment.

†Urine samples from six control and five surgically ligated fetuses.

laboratory. Fig. 1 shows the arginine vasopressin concentrations in the amniotic fluid before and after the injection of 25 μg arginine vasopressin into the amniotic cavity in the two groups of fetuses. Although the changes with time were highly significant ($p < 0.00001$) there was no difference between the control and ligated animals in amniotic fluid concentrations of arginine vasopressin at any time throughout the experiment.

The fetal plasma arginine vasopressin concentrations are presented in Fig. 2. Significant increases ($p < 0.00001$) were observed in both groups as early as 10 minutes after arginine vasopressin injection. Although plasma arginine vasopressin concentrations in the fetuses with esophageal ligation were on average higher than those in the control fetuses, there was no statistically significant difference between the two groups.

Fig. 3 shows the changes in fetal arterial pressure, venous pressure, and heart rate after the injection of arginine vasopressin. Significant increases occurred in arterial pressure ($p < 0.00001$) and there were no significant differences between groups. When the two groups were analyzed individually, arterial pressure increased significantly at 10 minutes in the ligated group and at 20 minutes in the control group. The venous pressure increased ($p < 0.003$) and showed no intergroup differences. The fetal heart rate decreased significantly ($p < 0.00001$) with changes occurring at 15 minutes in the ligated group and at 20 minutes in the control group. These heart rate changes were similar between the two groups.

In the animals from which urine was available, urine

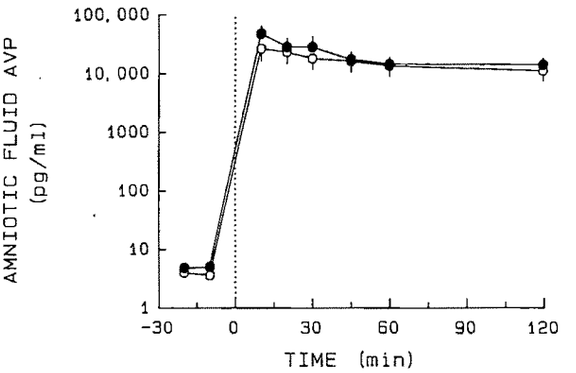

Fig. 1. Mean (±SEM) amniotic fluid arginine vasopressin *(AVP)* concentrations (log scale) after injection of 1 to 25 μg of arginine vasopressin into the amniotic cavity *(dotted vertical line)*. Changes from the control period are highly significant ($p < 0.00001$) for both the control and surgically ligated groups. *Closed circles* represent surgically ligated fetuses, *open circles* represent control animals.

arginine vasopressin concentrations (Fig. 4) increased significantly ($p < 0.0001$) with no difference between the control and ligated groups. The rise occurred within 45 minutes in both groups. Urine osmolality, sodium ion, and chloride ion increased (Fig. 5) concurrently with the increases in urine arginine vasopressin concentrations. Urine osmolality increased significantly ($p < 0.0001$) and the rise occurred in both groups by 45 minutes. Urine sodium and chloride ion concentrations increased significantly ($p < 0.0001$) at 45 minutes in both groups with no intergroup differences. Fetal urine flow rate (Fig. 6) decreased ($p < 0.001$) similarly in both groups of fetuses and there was no difference between the two groups.

The fetal plasma pH decreased significantly in both groups at two hours after the injection ($p < 0.01$), and there was no difference between groups. The fetal plasma P_{CO_2} values increased significantly by 1 mm Hg at 2 hours after the injection ($p < 0.05$) and there was no difference between the two groups. The fetal pO_2 value did not change in either group. There were no significant changes in any of the other fetal or maternal parameters after the injection of arginine vasopressin.

The amniotic fluid osmolality increased ($p < 0.001$) similarly and significantly in both groups after the arginine vasopressin injection. This occurred simultaneously with the increase in urine osmolality and arginine vasopressin concentration. The amniotic sodium and chloride ion concentrations increased significantly ($p = 0.05$ for sodium, $p < 0.01$ for chloride) by the second hour after the injection in parallel with amniotic osmolality with no difference between groups.

Comment

In this study we showed that arginine vasopressin (molecular weight of 1084 daltons) can rapidly enter

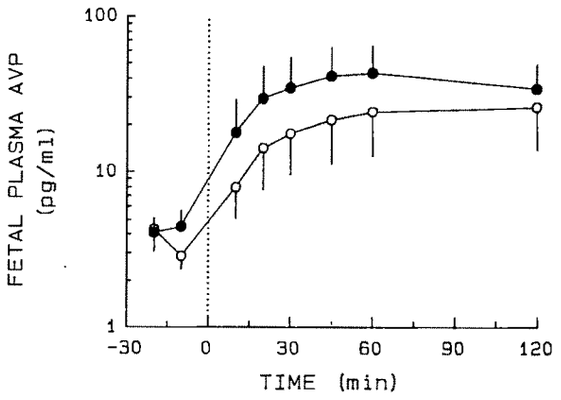

Fig. 2. Mean (±SEM) fetal plasma arginine vasopressin *(AVP)* concentration (log scale) after injection of 1 to 25 μg of arginine vasopressin *(dotted vertical line)* into the amniotic cavity. Both groups (*closed circles* represent surgically ligated, *open circles* represent control) had significant increases ($p < 0.0001$, ligated; $p < 0.002$, control) and were not different from each other.

the fetal circulation through the intramembranous pathway independent of fetal swallowing. Furthermore, this absorbed arginine vasopressin has physiologic activity as manifested by pronounced effects on both the cardiovascular and renal systems. Finally, these observations suggest that the intramembranous pathway may be the major route for uptake of arginine vasopressin from the amniotic cavity into the fetal circulation.

Arginine vasopressin secretion is generally enhanced during fetal stress. In addition to its cardiovascular actions, arginine vasopressin acts on the fetal kidney to increase the reabsorption of water and cause excretion of a more concentrated urine. During the time when plasma arginine vasopressin levels are elevated, urine contains high levels of arginine vasopressin, which enters the amniotic cavity, and amniotic arginine vasopressin concentration increases. The levels of amniotic arginine vasopressin remain elevated for periods of up to 24 hours after acute hypoxia or arginine vasopressin injection into the amniotic cavity of fetal sheep.[7] To what degree arginine vasopressin normally exchanges directly between fetal blood and the amniotic fluid is unknown. However, in three of six control fetuses during the preinjection period in our study, fetal urine arginine vasopressin concentration was the highest with fetal plasma lowest and amniotic fluid arginine vasopressin concentration intermediate. If amniotic fluid arginine vasopressin was removed only by swallowing, one may expect that amniotic fluid arginine vasopressin would equal urine arginine vasopressin under basal conditions. With a lower amniotic fluid arginine vasopressin concentration than that of urine, arginine vasopressin appears to leave the amniotic compartment by some route other than swallowing. This is further supported by the observation that in three of five ligated fetuses under basal conditions, the same urine-amniotic-plasma concentration profile existed as above. This, of course, assumes that enzymatic degradation of amniotic arginine vasopressin was slight as suggested by persistent elevations in amniotic arginine vasopressin in other studies in sheep.[7]

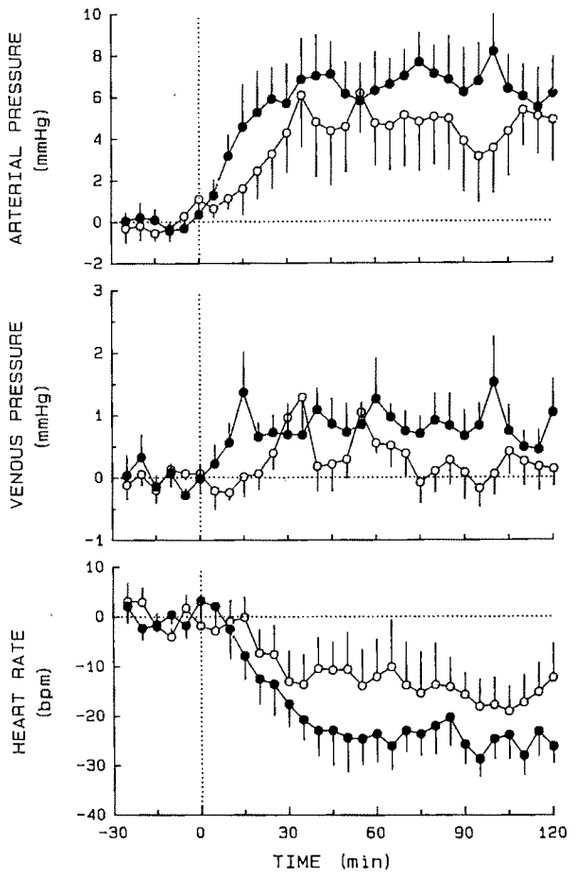

Fig. 3. Mean (±SEM) change from control in fetal arterial pressure *(upper)*, venous pressure *(middle)*, and heart rate *(lower)*. *Closed circles* represent the surgically ligated fetuses, *open circles* represent control fetuses. Arterial pressure increased significantly in both groups ($p < 0.00001$, ligated; $p < 0.002$, control) and were not different from each other. Venous pressures increased significantly ($p < 0.0001$, ligated; $p < 0.003$, control) and were not different from each other. Fetal heart rate decreased significantly in both groups ($p < 0.00001$, ligated; $p < 0.02$, control) and were not different from each other. *Dotted vertical line* is time of injection.

In our earlier study[1] we found that the conductance of the intramembranous pathway to amniotic water was increased with ligation of the fetal esophagus and we believed that this could possibly explain the finding of occasionally normal amniotic fluid volumes in the absence of fetal swallowing.[11, 12] This study is not inconsistent with the concept of an increase in conductance of the intramembranous pathway to amniotic arginine vasopressin after esophageal ligation because in every measured parameter (Figs. 1 to 6) the ligated animals had a larger response than that of the control animals.

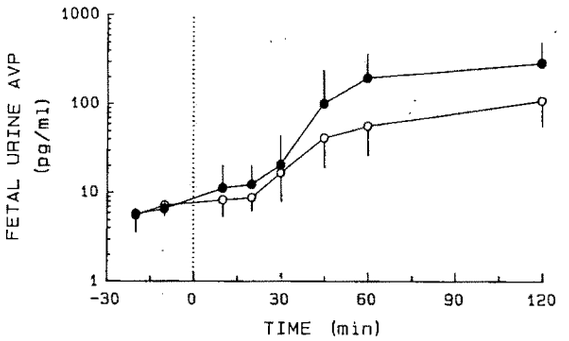

Fig. 4. Mean (±SEM) fetal urine arginine vasopressin *(AVP)* concentration (log scale) after injection of 1 to 25 μg *(dotted vertical line)* into the amniotic cavity. Both groups had significant increases ($p < 0.0001$, control; $p < 0.0001$, ligated) and were not different from each other. *Closed circles* represent surgically ligated fetuses, *open circles* represent control fetuses.

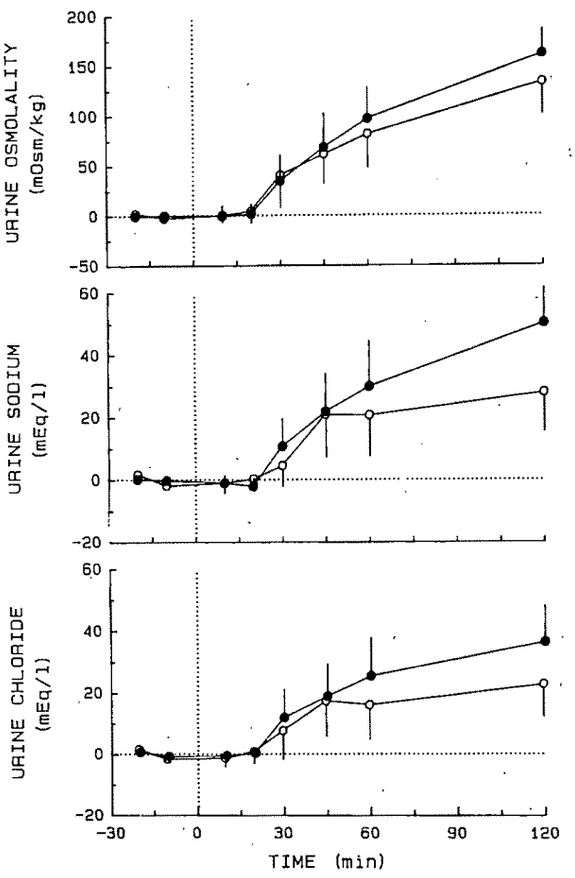

Fig. 5. Mean (±SEM) change in fetal urine osmolality and sodium and chloride ion concentrations after injection of arginine vasopressin *(dotted vertical line)* into the amniotic cavity. Both groups showed significant increases in urine osmolalities after injection of arginine vasopressin and were not different from each other. *Closed circles* represent surgically ligated ($p < 0.0001$), *open circles* represent control ($p < 0.001$). Both groups of animals showed significant increases in urine sodium ($p < 0.0001$) and urine chloride ($p < 0.0001$) and were not different from each other.

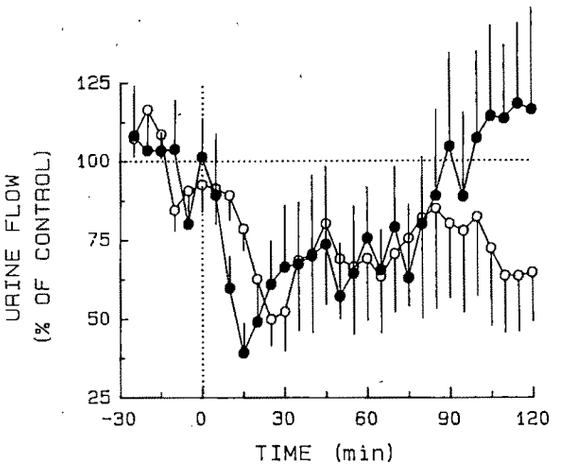

Fig. 6. Mean (±SEM) change from control urine flow after injection of arginine vasopressin *(dotted vertical line)*. Both groups had significant decreases in urine flow ($p < 0.001$) and were not different from each other. *Closed circles* represent ligated fetuses, *open circles* represent control fetuses.

Individually there were no statistically significant differences between the groups, but collectively there was a tendency for a greater response in the ligated animals.

We used the same experimental protocol as Ervin et al.[7] and found similar significant increases in fetal plasma and urine arginine vasopressin concentrations as well as increases in urine osmolality and urinary sodium. In contrast to their finding of no changes, we found highly significant increases in fetal arterial pressure and decreases in heart rate and urine flow. However, their Table I showed nonsignificant changes in these variables in the same direction as in this study. Presumably the difference in statistical significance is a result of better resolution of the data with our on-line data acquisition system. However, in contrast to their conclusion that amniotic arginine vasopressin was absorbed by fetal swallowing, we observed essentially identical changes in fetuses with ligated esophagi. Because swallowing could not have been the cause of the increase in fetal plasma arginine vasopressin concentration in the ligated animals, it appears that the intramembranous pathway may be the primary route for amniotic arginine vasopressin to enter the fetal circulation.

The fetal cardiovascular responses obtained in this study are similar to those found during intravascular infusions of arginine vasopressin when comparable plasma concentrations of arginine vasopressin were achieved.[5, 13] Thus the absorbed arginine vasopressin retained its biologic activity. In comparison, the gastrointestinal system might be expected to degrade swallowed arginine vasopressin.

Our results showed that the changes in all urinary parameters except urine flow were delayed in relation

to the cardiovascular and plasma arginine vasopressin concentrations. This was due to a delay in collection of urine samples that passed through the tubing and a roller pump before sampling. Furthermore, there is a natural delay in the urine collection that must leave the kidney and enter the bladder before being sampled. Thus the urine changes may have occurred simultaneously with changes in the other variables. In Fig. 6 the urine flow in the ligated group returns to control values at 90 minutes after the injection into the amniotic cavity, whereas the control urine flow stays depressed. This finding is consistent with findings of Lingwood et al.[6] who reported a decrease in urine flow at low doses of arginine vasopressin infused into the fetal circulation, but an increase in urine flow at higher dosages. They believed that the increase in urine flow was a result of an arginine vasopressin presser effect that overrides the renal effect.

Collectively, the previous study and this study suggest that the intramembranous pathway may be the primary route by which amniotic fluid arginine vasopressin reenters the fetal circulation. The assumption that arginine vasopressin is representative of similar or smaller molecular weight substances suggests that the intramembranous pathway may play a major role in the regulation of amniotic fluid volume and composition.

Discussion

DR. ROBERT CREASY, Houston, Texas. Amniotic fluid regulation has been a source of many questions, investigations, and theories for decades. This current investigation studies the movement of biologically active arginine vasopressin from the amniotic cavity of the chronically instrumented pregnant ewe. One half the animals studied also had the fetal esophagus doubly ligated to interfere with fetal swallowing of amniotic fluid and the uptake of its components, including the exogenously derived increase of arginine vasopressin. I presume that at autopsy the authors confirmed that the esophagi of these fetuses were not patent. The results appear to clearly show that the arginine vasopressin injected into the amniotic cavity quickly (within 10 minutes) resulted in an increase in fetal plasma arginine vasopressin. This increase in fetal plasma arginine vasopressin was then associated with a number of known biologic responses within the fetus. There were no detectable differences noted between the fetuses with ligated esophagi compared with those not ligated. However, it is interesting to note that there were consistent trends to greater responses in fetal plasma arginine vasopressin, arterial and venous pressure, heart rate, urine arginine vasopressin, urine osmolality, and urine sodium in the ligated fetuses. Perhaps the authors could speculate on why such pronounced consistent trends for greater responses were present in the esophageal ligation group. Also noteworthy is the return to normal in urine flow at 90 to 120 minutes in the esophageal ligation group, a feature not present in the nonesophageal ligation group. These experiments and previous ones by these authors indicate that not only water but other components of amniotic fluid may be rapidly absorbed by a intramembranous pathway into the fetal circulation in the ewe and have biologic activity at the gestational age studied.

The increase in arginine vasopressin in fetal plasma results in an increase in urinary arginine vasopressin and a continuing increase in amniotic fluid arginine vasopressin. Previous experiments indicate the amniotic fluid arginine vasopressin concentrations may remain elevated for 24 hours. Presumably, this arginine vasopressin may recirculate again into the fetal circulation via the transmembranous pathway and remain biologically active inasmuch as all their experimental variables remain altered at 120 minutes except for one, namely urinary flow. The curious result is that urinary flow returned to normal by 90 minutes in fetuses with esophageal ligation, yet urinary flow in the control

group remained depressed. I would appreciate if the authors could theorize why urinary flow is normal after 90 minutes in the group of fetuses with esophageal ligations when all other experimental variables in both groups remain changed at up to 120 minutes. How long does arginine vasopressin remain biologically active and in what compartments?

A small point that needs to be addressed is the radioimmunoassay for arginine vasopressin. An interassay coefficient of variation of 16% seems somewhat excessive.

Last, I wonder whether the authors believe that the intramembranous pathway is operable in human gestation? Could such a pathway involve other substances such as α-fetoprotein, steroids, and monokines.

Dr. Sheldon H. Cherry, New York City, New York. In the late 1960s we did some work at Mt. Sinai on elucidating the mechanism for bilirubin transport into the amniotic cavity in erythroblastosis. It was our thesis that bilirubin in amniotic fluid is unconjugated bilirubin and it was related to the protein content in the amniotic fluid. We could put protein (albumin) into the amniotic fluid cavity and thereby raise the bilirubin content. This we believed showed the efficacy of the intramembranous area for transport and relates to this article.

It was our thesis that the umbilical cord vessels (and the fetal surface of the placenta) were important transport sites as was mentioned in your article. I would like your opinion on this question.

REFERENCE

Dr. Warren M. Crosby, Oklahoma City, Oklahoma. It was not clear in the abstract or in the article whether the control animals were sham operated. If the control animals had no surgical exploration in the neck, I think the conclusion you drew might be invalid. When operating in the neck there are chemoreceptors and baroreceptors that are disturbed and that may release autonomic vasoactive substances.

Dr. R. Besinger, Maywood, Illinois. I congratulate Dr. Gilbert on a provocative study, but I have a question. We all know that fetal sheep breathe, and I am curious whether the author would like to address the issue of a potential pulmonary pathway for transmission of these substances from the amniotic fluid.

Dr. Thomas H. Kirschbaum, Los Angeles, California. Dr. Gilbert, I wonder whether you measured maternal arginine vasopressin concentration in the course of this work. I understand you have excluded the possibility of transmission from amniotic fluid to the mother and then across the placenta to the fetus on morphologic grounds dealing with the localized maternal perfusion in the sheep. But I wonder whether you checked it by following up the concentrations in the maternal blood.

Dr. Robert Barbieri, Stony Brook, New York. In human beings arginine vasopressin is well absorbed across nasal and conjunctival membranes. In fact, that is the way it is administered for therapy. I wonder whether the authors looked at the possibility that the oral membrane, conjunctive or nasal mucosa, are roots of absorption of arginine vasopressin.

Dr. John P. Gusdon, Jonesboro, Georgia. I just had a déjà vu of some work done around 30-some years ago at the University of Virginia by Dr. Harry Gaughey. You asked some of the same questions, although his work was in vitro. I would like to know what method was used in your study to measure arginine vasopressin.

Dr. Gilbert (Closing). At autopsy we documented the nonpatency of all the ligated esophagi. One point I did not address in my discussion was the tendency toward an increase in the fetal plasma arginine vasopressin concentrations as well as a change in all the parameters measured was seen in the ligated group as compared with controls.

In our original water-injection study, we found that there was an increase in absorption of water with the ligation of the fetal esophagus. When we estimated the amount of water movement, we found that under normal physiologic conditions about 200 ml per day would go from the amniotic cavity into the fetal circulation. That happened to almost exactly equal the differences found between fetal urination and fetal swallowing in multiple animal and human studies.

In our study we found that with the injection of the arginine vasopressin into the amniotic cavity we did not find a statistically significant increase in conductance of the intramembranous pathway.

However, I do believe that tendency probably is there. If an increase in water absorption is found with the ligation of the fetal esophagus, it would make sense to me that there would be an increase in arginine vasopressin absorption either by diffusion or with the bulk flow of water. So I think that finding those tendencies toward an increase is consistent with our previous water finding. That we did not have enough of a difference to make a statistical difference is interesting.

The question about the return to normal on the urine flow in the ligated group is interesting. One of the first mechanisms of arginine vasopressin action on the kidney is a decrease in urine flow, which we found. If you remember from Fig. 6, the initial drop in urine flow in the ligated group was the most significant initially.

Arginine vasopressin increases blood pressure, and in the ligated group there is a higher rate of increase in blood pressure, both arterial and venous, as compared with the control group. At some point there is an overriding effect of blood pressure on the kidneys and you have an increase in urine flow. I was not surprised that there was a return to normal and then an increase in urine flow as the pressure head on the kidney increased.

The half-life of arginine vasopressin in fetal plasma has been reported to be about 5 to 15 minutes. Few

studies have looked at the half-life in amniotic fluid in the amniotic cavity. Several authors have found that after injection into the amniotic cavity arginine vasopressin is still markedly elevated at 24 hours. There is decreased arginine vasopressinase activity present in the amniotic cavity.

With regard to the question about the human applications, even though the sheep placentation is markedly different from that of human beings in multiple ways, there are many reports in the literature of either primates or human beings of injections of substances into the amniotic cavity and these substances being found at the time of the cesarean section with elevations in cord levels that could not be explained by fetal swallowing. Fetal swallowing has been shown to occur in bouts of two to seven times a day at varying volumes.

So we believe that in human beings, even though it is a different placentation, the back side of the placenta is fairly large in utero and is exposed to multiple fetal vessels. I believe that potentially in the future pharmacologic agents such as digoxin may be used for fetal cardiac arrhythmias. Other substances such as thyroid hormone, or thyrotropin-releasing factor or steroids may be used for the lung maturation.

Dr. Cherry brought up the bilirubin transport and the umbilical cord. Many authors have looked in vitro at perfusing umbilical cords and at exposing them to radioactive-labeled substances. They found that there was absorption into the umbilical cord. I consider this as probably part of this overall pathway of absorption.

If you think about it from a physiologic viewpoint, minimal absorption across the umbilical cord occurs because you have got a cord with a fairly large distance across Wharton's jelly to the umbilical vessels, coupled with a high blood flow and minimal area of absorption. However, some in vitro studies found that the umbilical cord is a route for passage of labeled substances; and bilirubin very well could be that way.

No, Dr. Crosby, we did not do sham operations at the time of initial surgery. What we basically did was brought the fetal head out, made a vertical incision, found the esophagus, double ligated it, sewed it back up, and put it back in. We did not believe that the sham operation was needed. You are right, however, that to be a true control we would have needed to sham operate those animals.

The question about fetal breathing was brought up. We know that in utero it used to be thought that fluids went into the fetal lungs throughout fetal development. We know that with fetal breathing movements, larger volumes can move back and forth with every episode of fetal breathing. But when you look at an overall summation, a net outward movement of fluid occurs. In fetal sheep about 20% of fetal body weight per day is excreted through the fetal lungs. Absorption by the lungs is minimal if at all for the above reasons.

The question raised about the nasal route for absorption is a very good question. There was a report from San Francisco in the literature about digoxin being injected into the amniotic cavity (Hamamoto K, Iwamoto HS, Roman CM, Benet LZ, Rudolph AM. Fetal uptake of intraamniotic digoxin in sheep. Pediatr Res 1990;27:282-5). They measured umbilical vein levels of digoxin and dorsal aorta levels of digoxin. They found in 10 of the 11 animals that the level in the umbilical vein was less than the level in the dorsal aorta. They found a very rapid absorption into the fetal circulation. This higher dorsal aorta level than vein digoxin level made us think, are we completely wrong? What other route of absorption is there? Then we realized that in adults the nasal passage is a tremendous route for absorption of vasopressin as well as other substances.

In utero the fetal sheep is in a fetal position, and our catheters are attached to the legs close to the nose. This could have been a potential route of absorption.

To test this, very recently we put a surgical glove over the ovine fetal head. In five animals we injected arginine vasopressin in the amniotic cavity, and in five we injected it into the glove over the head. We found in the five with injections into the amniotic cavity the exact same thing we found here with the ligated group. In the group with the injection into the glove we found absolutely no change in the cardiovascular parameters. Plasma concentrations of arginine vasopressin have not been measured. I am comfortable that we have ruled out the nose as a possible route of absorption.

I cannot explain the findings of a level of dorsal aorta digoxin higher than that in the umbilical vein.

There was a question about the radioimmunoassay. Dr. Creasy had a question about coefficient of variation being 16%. The radioimmunoassay for this assay I found to be fairly consistent with that in the literature when you measure arginine vasopressin. The intraassay variation is about 4% to 5% and the interassay variation was 16% as you reported.

With regard to an earlier question, there were no differences or changes in maternal levels of arginine vasopressin measured.

Effect of intravenous cocaine on uterine blood flow in the gravid baboon

Cocaine abuse during pregnancy is associated with adverse perinatal outcome, believed to be a result of potent vasoconstrictive effects that cocaine has on the maternal cardiovascular system. The direct effect of cocaine on the pregnant, nonhuman primates' uterine vasculature in vivo has not been examined. We investigated the effects of intravenous cocaine on maternal arterial blood pressure, uterine blood flow, and uterine vascular resistance in four unanesthetized, chronically instrumented pregnant baboons. Baboons were instrumented during the latter half of pregnancy, placing an ultrasonic flow probe around one uterine artery and cathethers in the maternal inferior vena cava and aorta. Bolus intravenous cocaine hydrochloride doses of 0.05 mg/kg, 0.1 mg/kg, and 0.3 mg/kg by maternal weight were infused 30 minutes apart at least 5 days after surgical instrumentation. The maternal blood pressure rose 7.3% and 12.0% after the 0.1 mg/kg and 0.3 mg/kg cocaine infusions, respectively, and the uterine blood flow fell in a dose-dependent fashion 13.1% and 22.7%. Plasma norepinephrine levels rose in response to the 0.3 mg/kg cocaine infusion. These studies show that low doses of cocaine significantly reduce uterine blood flow in the pregnant baboon in a dose-dependent manner by increasing uterine vascular resistance. (Am J Obstet Gyneco. 1991;164:1021-30.)

Key words: Cocaine, uterine blood flow, pregnancy, baboon

Cocaine hydrochloride, as an illicit drug, is abused by 8% or more gravid women.[1] As a local anesthetic, it blocks the presynaptic reuptake of norepinephrine and dopamine, allowing these neurotransmitters to accumulate in the postsynaptic cleft and in the systemic circulation.[2-4] Thus the sympathetic nervous system is stimulated, resulting in systemic vasoconstriction, tachycardia, ventricular arrhythmias, and seizures.[5] The adverse perinatal outcomes observed in gravid women who abuse cocaine include intrauterine fetal growth retardation, congenital anomalies, preterm labor, abruptio placentae, and spontaneous subarachnoid hemorrhage are believed to be a result of profound systemic vasoconstriction.[1, 6-10] Recently this belief has been supported by investigators who observed a dose-dependent reduction of uterine blood flow in response to intravenous cocaine administered to the gravid ewe.[11-12] Although these investigations have significantly contributed to our understanding of its effect on the ewe's maternal-fetal unit, cocaine's effect in vivo on the unanesthetized, chronically instrumented, gravid nonhuman primate has not been previously reported. The purpose of this study was to determine cocaine's effect on hemodynamic parameters in the unanesthetized, chronically instrumented, gravid baboon in the third trimester of pregnancy.

Material and methods

Four pregnant baboons *(Papio cynocephalus/anubis)* at 90 to 121 days' gestation (term, 175 days) from the nonhuman primate colony maintained at the University of Oklahoma Health Sciences Center were used for this study. The animals were transported from the colony site to the Biomedical Sciences Building animal care facility approximately 3 weeks before surgical instrumentation. On arrival, the animals were individually caged in sight of at least one other baboon in a lighting cycle environment of 14 hours light and 10 hours dark with lights on at midnight. Fresh water, high-protein monkey chow (Purina Mills, Inc., St. Louis), and fresh

fruit were provided daily to the baboons to eat as desired. A jacket (Alice King Chatham, Medical Arts, Los Angeles) was placed on each baboon while under light anesthesia induced by ketamine 1 week before a training tether and swivel system were attached to the jacket.

After 2 weeks of acclimation to this relatively unrestricted freedom of movement, surgical instrumentation was performed. The animals were anesthetized with intramuscular ketamine (10 mg/kg) and xylazine (0.5 mg/kg) and positioned in left lateral tilt on an operating table equipped with a warming blanket. Fetal viability was ascertained by stethoscope auscultation of the fetal heart rate. Two baboons were maintained on a continuous intravenous ketamine infusion of 0.23 to 0.28 mg/kg per minute and oxygen at a flow rate of 2 L/min administered by means of a muzzle cone. The remaining two baboons underwent endotracheal intubation and were maintained during surgery with halothane (0.75 to 1.5%) and oxygen (2 L/min) by means of an Ohio 930 Metometic anesthesia machine (Ohnedia, Madison, Wis.) Through a groin incision cathethers were placed into the aorta via a branch of the superficial femoral artery for measurement of maternal arterial blood pressure and sampling of circulating hormone concentrations, and into the inferior vena cava via a branch of the superficial femoral vein for intravenous drug administration. A muscle-splitting incision was performed in either the left or right flank to enter the pelvic retroperitoneal space. The ipsilateral external and internal iliac and uterine arteries were exposed through blunt and sharp dissection. A 2 mm pulse transit-time ultrasonic flow probe (Transonic Systems, Inc., Ithaca, N.Y.) was placed around the uterine artery. The groin and flank incisions were closed and the two vascular cathethers, and flow probe leads were tunneled subcutaneously to exit the baboon's back between the scapulae. The baboons were postoperatively maintained on a modified jacket, tether, and swivel system previously described by Stark et al.[13] This system allows for passage of the vascular catheters and flow probe leads through the roof of the cage. A box attached to the tether, anchored to the jacket on the baboon's back, contained the transducer to record arterial pressure (Cobe, Lakewood, Colo.). The vascular cathethers were flushed daily with 3 to 5 ml of 10 IU/ml heparinized saline solution.

Continuous acquisition of uterine blood flow and arterial pressure waveforms was performed with a custom-built computer-based data acquisition system. Briefly, signals are sampled at 32 Hz. The average value during 8 seconds is digitized and stored on an IBM computer with a time signal. The 32 Hz sampling frequency prevents aliasing problems with changing signals; however, the storage rate of one reading every 8 seconds allows for manageable data analysis. Details of this data acquisition system have been previously described.[14, 15]

All studies were conducted at least 5 days after surgical instrumentation. Cocaine hydrochloride (Sigma Chemical Company, St. Louis) in doses of 0.05, 0.1, and 0.3 mg/kg by maternal weight was dissolved in 5 ml of 0.9% saline solution. For each experiment the unanesthetized baboon was monitored continuously for a 45-minute baseline period before cocaine administration. During this period, arterial blood samples were taken for baseline catecholamine determinations 45, 30, and 15 minutes before cocaine administration. Each cocaine dose was administered intravenously over 30 seconds as a bolus. The 0.05 mg/kg cocaine dose was followed at 30-minute intervals by the 0.1 mg/kg and 0.3 mg/kg cocaine doses on one day. Arterial blood samples were taken for catecholamine determinations at 5 and 10 minutes after the 0.05 and 0.1 mg/kg cocaine doses and at 5, 10, 15, and 30 minutes after the 0.3 mg/kg cocaine dose. Maternal blood pressure and uterine blood flow were continuously monitored throughout the 90-minute study period.

For data analysis, maternal arterial blood pressure and uterine blood flow measurements were made 5 minutes before the initial cocaine infusion and 1, 2, 5, 10, 15, and 30 minutes after cocaine infusion. The 1- and 2-minute measurements represent all the data points over the period. Measurements at the other times represent all the data points (obtained every 8 seconds) for 1 minute before and 1 minute after the chosen time. Uterine vascular resistance was determined by the equation: UVR = MAP/UBF, where UVR = uterine vascular resistance, MAP = mean arterial pressure, and UBF = uterine blood flow. This study was reviewed and approved by the Institutional Animal Care and Use Committee of the University of Oklahoma before initiation of the protocol.

Plasma catecholamines were measured by high-performance liquid chromatography with a 0.1 mol/L sodium acetate, 0.5 mmol/L ethylenediaminetetraacetic acid, 2.5 mmol/L hepatane sulphonic acid, and pH 5.2 mobile phase at a flow rate of 1.6 ml/min. After initial filtration and degassing, a continuous helium purge was maintained in a mobile-phase reservoir to eliminate dissolved oxygen. The reversed-phase c-18 column (Biophase ODS 25 cm, 5 μ particle size; Bioanalytical Systems Inc., West Lafayette, Ind.) was kept at 23° C. The dual electrode LC-4B amperometric detector (Bioanalytical Systems) was used at an applied potential of 625 and 675 mV in the oxidation mode with

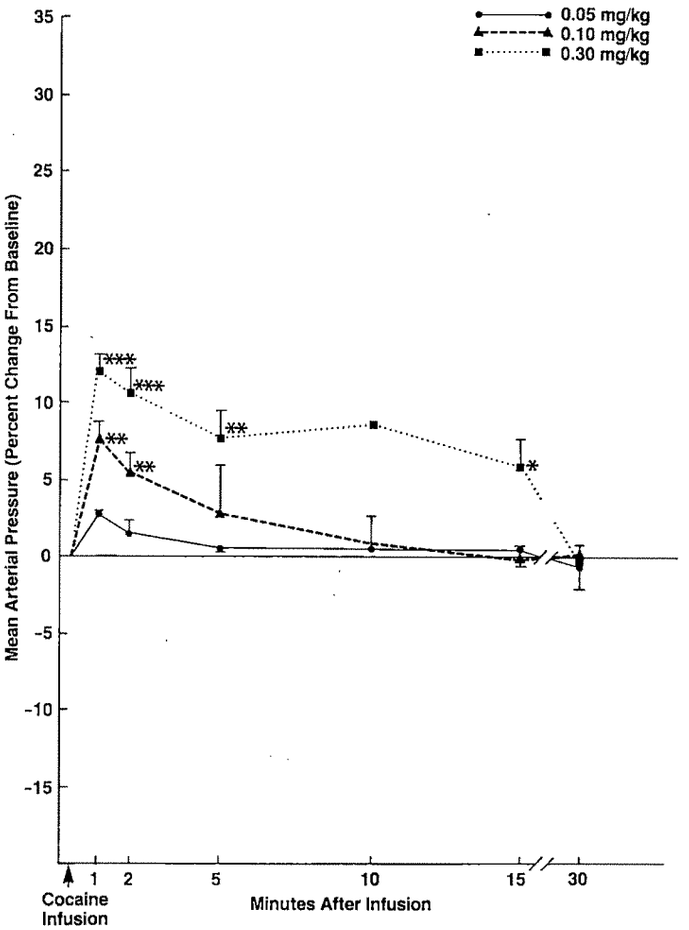

Fig. 1. Maternal mean arterial pressure responses to intravenous cocaine in the pregnant baboon at 97 to 126 days' gestation (n = 3). The following symbols represent the cocaine doses infused: ●—● 0.05 mg/kg; ▲–▲ 0.1 mg/kg; ■. . .■ 0.3 mg/kg. *Single asterisk* indicates $p < 0.05$; *two asterisks*, $p < 0.025$; and *three asterisks*, $p < 0.01$.

the gain set a 1 and 2 nA full scale deflection. A standard solution containing 500 pg of norepinephrine, epinephrine, L-dopa, dihydroxybenzylamine, and 1000 pg of dopamine and butanephrine in 200 μl of 0.1 mol/L perchloric acid was injected into every fourth sample to evaluate the chromatography conditions and for calculations. Linearity of the detection system was evaluated between 25 and 500 pg of catecholamine injected. On the basis of the signal-to-noise ratio the limit of detection was 50 pg injected for injected norepinephrine, epinephrine, and dihydroxybenzylamine. Plasma (0.5 to 1 ml) was precipitated with an equal volume of 0.6 mol/L perchloric acid, mixed and centrifuged at 2000 rpm for 10 minutes at 4° C. The supernatant was collected and stored frozen at −80° C until assayed. The acid supernatant (0.5 to 1 ml) was neutralized with 50 to 100 μl of 3 mol/L sodium hydroxide, and 25 mg of acid washed alumina (Bioanalytical Systems), 50 μl of a solution containing 625 pg of 3,4-dihydroxybenzylamine and 1 ml of 1.5 mol/L Tris hydrochloride buffer pH 8.5 were added and mixed. The extraction was carried out by shaking the mixture in a 4 ml capped conical polystyrene vial (Evergreen, Los Angeles) in a horizontal shaker for 10 minutes. After three washes with distilled water, the alumina was transferred to a filter tube assembly (Spinx Costar, Cambridge, Mass.) and centrifuged at 12,000 rpm for 2 minutes. The filter containing the dry alumina was washed with 250 μl of 0.1 mol/L perchloric acid. The perchloric acid containing the catecholamines was separated by centrifugation at 12,000 rpm for 2 minutes and transferred to an injection vial fitted with a small-sample insert (Waters Intelligent Sample Processor, Waters Associates, Milford, Mass.). The inter-

assay variability was 6.5% and 10% for norepinephrine and epinephrine, respectively.

Data are reported as mean ± SEM. Statistical analysis was performed by the paired Student t test and the two-tailed independent Student t test where appropriate. Significance was set at $p < 0.05$.

Results

The mean ± SD gestational age of the pregnant baboons at the time of cocaine infusion was 115 ± 14 days. The effects of intravenous cocaine infusions on mean arterial pressure are illustrated in Fig. 1. The 0.05 mg/kg dose had no effect on the baboons' arterial blood pressure whereas the 0.1 and 0.3 mg/kg doses both resulted in significant elevations of the baboons' arterial blood pressure. The degree and duration of arterial blood pressure elevation were dose-dependent (Fig. 1).

The effects of intravenous cocaine on uterine blood flow are illustrated in Fig. 2. No significant change was observed in the uterine blood flow after the 0.05 mg/kg dose. However, significant dose-dependent reductions in uterine blood flow were observed in response to both the 0.1 and 0.3 mg/kg doses (Fig. 2). The maximal reduction of uterine blood flow appears to be dose-dependent, it was 13.1% 5 minutes after the 0.1 mg/kg dose, and 22.7% 15 minutes after the 0.3 mg/kg dose.

Uterine vascular resistance was calculated for each cocaine dose infused (Fig. 3). As previously observed with the mean arterial pressure and uterine blood flow, no significant change in uterine vascular resistance was

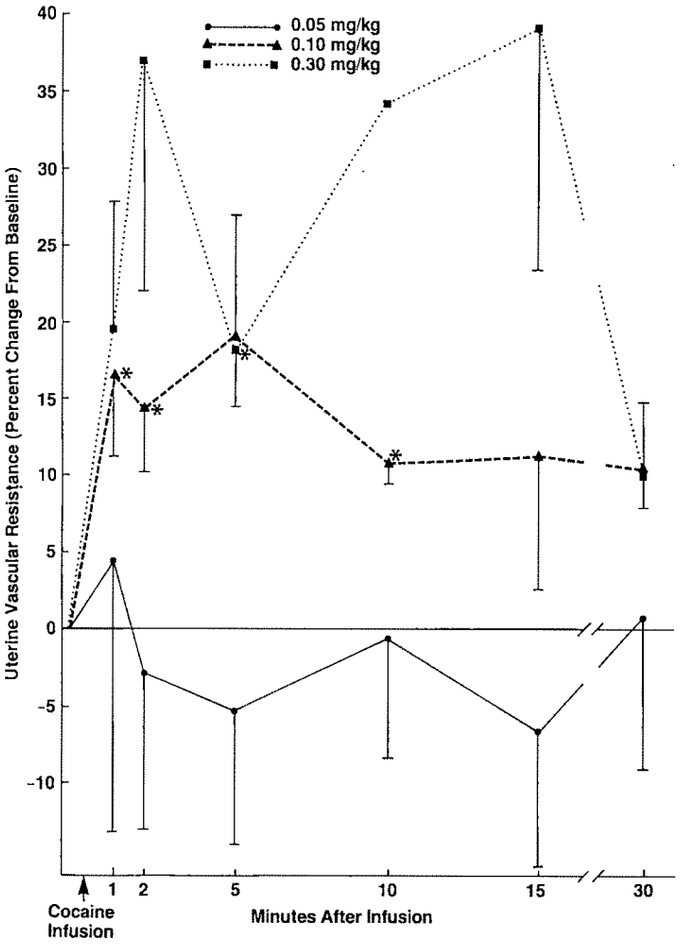

Fig. 3. Responses of uterine vascular resistance to intravenous cocaine in the pregnant baboon at 97 to 126 days' gestation (n = 3). The following symbols represent the cocaine doses infused: ●—● 0.05 mg/kg; ▲–▲ 0.1 mg/kg; ■. . .■ 0.3 mg/kg. *Single asterisk* indicates $p < 0.05$.

observed after the 0.05 mg/kg dose infusion. A significant increase in uterine vascular resistance was observed after the 0.1 and 0.3 mg/kg dose infusions. The increased uterine vascular resistance appeared to be dose-dependent as observed by the mean arterial pressure and uterine blood flow response to cocaine with a maximal increase of 10.8% 5 minutes after the 0.1 mg/kg, and 39.0% 15 minutes after the 0.3 mg/kg dose was infused.

The responses of the pregnant baboons' arterial blood pressure, uterine blood flow, and uterine vascular resistance to intravenous cocaine appears to be at least partially reflected in increases in the systemic circulation of norepinephrine (Fig. 4). Although norepinephrine levels did not change after the 0.05 and 0.1 mg/kg cocaine infusions, the 0.3 mg/kg dose resulted in a 64% increase in the systemic norepinephrine level 15 minutes after the cocaine infusion. It is interesting that the observed increase in the baboons' arterial blood pressure and the fall in uterine blood flow after the 0.1 mg/kg cocaine infusion was without an increase in the systemic norepinephrine levels. The plasma epinephrine levels remained relatively unchanged from baseline levels after each cocaine infusion. However, none of these catecholamine levels achieved statistical significance.

Comment

Cocaine, administered intravenously to pregnant baboons, produces a dose-dependent rise in arterial blood pressure and uterine vascular resistance and a dose-dependent fall in uterine blood flow. These results show a similar dose-response to intravenous cocaine as has been observed in the pregnant ewe.[11, 12] In our

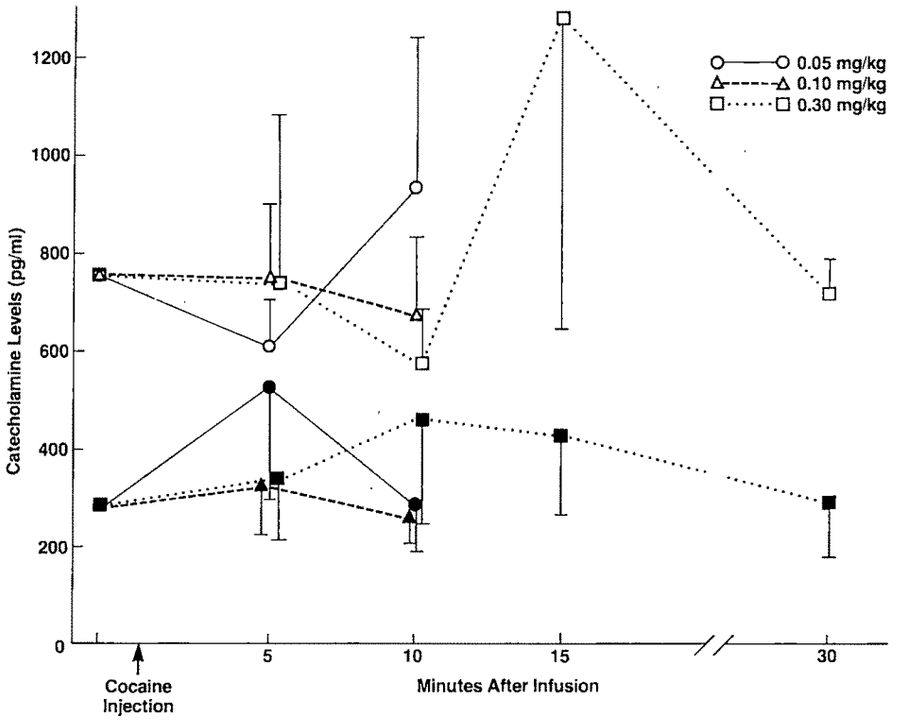

Fig. 4. Maternal catecholamine levels (norepinephrine, *open symbols;* epinephrine, *solid symbols*) in response to intravenous cocaine in the pregnant baboon at 97 to 126 days' gestation (n = 4). The following symbols represent the cocaine doses infused: ●—● 0.05 mg/kg; ▲–▲ 0.1 mg/kg; ■. . .■ 0.3 mg/kg.

study we used lower doses of cocaine than those that were administered in the studies with pregnant sheep.

The lowest cocaine dose infused into the maternal ewe by Moore et al.[11] was 0.3 mg/kg. This dose produced a 12% rise over baseline in maternal arterial blood pressure and a 30.4% fall from baseline in uterine blood flow. We similarly observed a peak rise of 12% in maternal baboon arterial blood pressure to occur 1 minute after the cocaine infusion (Fig. 1). The fall in uterine blood flow in the pregnant baboon, however, was not as marked as that observed in the maternal ewe (22.7% versus 30.4%). This small difference of uterine blood flow reduction is probably not significant but may be related to differences either in species or methods between the two investigations.

Although cocaine blocks the reuptake of norepinephrine at the presynaptic nerve terminal,[2] the relationship between the observed cardiovascular changes and systemic norepinephrine levels in response to cocaine administration have not been clearly elucidated.[17,18] Moore et al.[11] observed a doubling of systemic norepinephrine levels in response to a 0.5 mg/kg cocaine infusion in the maternal ewe; however, we observed a 64% increase in systemic norepinephrine levels in response to a lower cocaine dose (0.3 mg/kg). Our lack of a statistically significant increase in the norepinephrine level observed 15 minutes after the 0.3 mg/kg cocaine infusion could be a result of the small number of animals or a differing threshold effect in individual animals.

Even though a significant increase in maternal arterial blood pressure and fall in uterine blood flow was observed in the baboon after the 0.1 mg/kg dose, changes in systemically measured norepinephrine levels were not shown. This observation in the baboon may be related to either the absence of blood samples immediately after the cocaine administration or the failure of norepinephrine concentrations within the tissues to be reflected in the systemic circulation at this dose.

Local cocaine blockade of norepinephrine's reuptake may be enough to elicit vasoconstrictive action in uterine vasculature without any rise in systemic norepinephrine levels as we observed after the 0.1 mg/kg cocaine infusion. This presumed local effect of cocaine seems to be supported by the observations of Dolkart et al.[18] They showed in the pregnant ewe that α_1-

adrenergic receptor blockade with phenoxybenzamine hydrochloride ablated the maternal arterial blood pressure response to cocaine's administration, whereas the effect of cocaine on uterine blood flow was unchanged. In contrast, Moore et al.[11] reported that pretreatment with phentolamine (a partial α_1-adrenergic receptor blocker) did not change either the maternal blood pressure or uterine vascular response to infusion of cocaine. They speculated that cocaine may exert its vasoconstrictive effect through a mechanism that does not involve the α-adrenergic receptor. However, norepinephrine levels were not measured after both α_1-adrenergic receptor blockade and cocaine infusion.

In view of the differences in placentation and uterine blood flow in ruminants and primates it is important to obtain data in experimental situations from nonhuman primate experimental animal models. Our study illustrates that even low doses of intravenous cocaine administered to a primate species results in vasoconstrictive cardiovascular changes. Although there are reported physiological and placental differences between human and baboon pregnancies,[19,20] response of the pregnant baboon to cocaine most likely resembles that that occurs in the human pregnancy. Our observations of the pregnant baboon's response to intravenous cocaine lends support to the belief that systemic vasoconstriction is responsible for the adverse perinatal outcome observed in gravid women who abuse cocaine.[1,6-10] The nonhuman primate model used in this study provides an opportunity to improve our understanding of the hemodynamic responses to cocaine ingestion and the determination of cocaine's effect on the cardiovascular system, endocrine responses, and uterine contractility in pregnant nonhuman primates.

We are especially grateful to Willie Clagg for his assistance and wonderful care of the baboons used in this project, to Susan Jenkins for her assistance in data analysis, and to Teresa McCain, Tracey Young, and Karen Moore for their help with this article.

Discussion

Dr. Robert Resnik, San Diego, California. As of 1985, it was estimated that 30 million Americans had used cocaine as least once, and that 5 million were regular users.[1] Current data would also suggest that usage increase in the general population has been paralleled by that among women in the reproductive age group and those actually pregnant. These alarming and tragic statistics have led to numerous clinical studies over the past several years directed at defining the pregnancy outcomes of pregnant cocaine abusers and their offspring. Such reports show a broad spectrum of unto-

ward perinatal events including premature separation of the placenta, intrauterine growth retardation, preterm labor, fetal distress, neonatal neurobehavioral abnormalities, congenital malformations with a predilection of the genitourinary tract, and isolated reports consistent with fetal cardiovascular accidents.

In 1986, in an attempt to explore the physiologic impact of cocaine in pregnancy, Moore et al.[2] first reported the effects of intravenously administered cocaine on maternal and fetal cardiovascular hemodynamics in the chronically instrumented ewe. They first determined that the dose of cocaine required to produce blood levels in the sheep, similar to those observed in human users, was between 0.3 and 0.5 mg/kg body weight. After intravenous administration of these doses, they noted the rapid onset of sharp increases in maternal mean arterial pressure and a 30% to 40% decrease in uterine blood flow. Within 4 to 5 minutes of cocaine administration there were also significant increases in fetal mean arterial pressure. These findings were confirmed by Woods et al.[3] who also reported increases in uterine vascular resistance, fetal tachycardia, and hypoxemia.

The new findings by Morgan et al. are of obvious importance because they represent the first of their kind in a primate. It is apparent that the physiologic responses observed after cocaine administration in the baboon are quite similar in both magnitude and temporal relationship to those observed in pregnant sheep. Morgan et al. are to be commended for these ambitious studies. Any investigator who has worked with primates appreciates the complexities of maintaining chronic preparations and obtaining reliable data.

When the information that has thus far been obtained from both species is considered, a clearer picture of the pathophysiology of cocaine use in pregnancy begins to emerge. It seems plausible that cocaine produces its deleterious fetal effects by two mechanisms: first, by induction of profound decreases in uterine blood flow with resulting fetal hypoxemia; second, by its rapid placental transfer leading to intense fetal vasoconstriction. These physiologic observations in animal models are consistent with the clinical disorders that have been reported. One might further speculate that fetal vasoconstriction may play a role in the development of congenital defects, although why the genitourinary tract appears to be preferentially vulnerable in human beings remains to be clarified.[4] Recent information derived from a rat model exposed to intraperitoneal cocaine late in the period of organogenesis reveals the acute formation of hemorrhage and edema in the upper extremities, genital tubercle, and upper lip and nose.[5]

I have two questions for Dr. Morgan. The difficulty in obtaining continuous physiologic measurements in the baboon is readily apparent and acknowledged. Nevertheless, I am concerned that the number of observations for each data point never exceeds three or four, and that these data are then expressed as the mean ± SEM. Given this limitation in data points, I would appreciate it if you would comment further on the reliability of the observations.

My second question has to do with the mechanism of cocaine action. As you stated, cocaine has been shown to inhibit the reuptake of norepinephrine at the presynaptic nerve terminal. Moore et al. were unable to inhibit the cocaine-induced increase in mean arterial pressure or decrease in uterine blood flow by pretreatment with the α-blocker phentolamine. More recently, Dolkart[6] reported that α_1-adrenergic receptor blockade with phenoxybenzamine inhibited cocaine-induced maternal vasoconstriction but not the decrease in uterine blood flow. In light of this paradox, I wonder whether you would care to comment on these observations, with particular reference to the effects of cocaine on other neurotransmitters with vasoactive potential.

Again, I want to congratulate you for what surely were difficult and tedious studies. Although small in number, your observations strongly suggest a similarity in the physiologic response to cocaine in the sheep and baboon.

Dr. Steve N. Caritis, Pittsburgh, Pennsylvania. I do not believe you measured intrauterine pressure, but I wonder whether there were phasic changes in uterine blood flow that might indicate whether there was an increase in intrauterine pressure.

Also, the period of observations seemed to be about 30 minutes. Were any of these animals studied for longer periods of time to determine whether there was a delayed effect on any of the parameters you were measuring? Finally, what was the state of these animals?

Were they agitated or calm? Also, were they horizontal or upright?

Dr. James Woods, Rochester, New York. I would like to focus Dr. Resnik's question even a little bit more specifically. The fact that phentolamine and phenoxybenzamine have been unable to abolish completely the total uterine vascular effect of cocaine raises the possibility that cocaine is working through other neurotransmitters, such as dopamine.

About 2½ years ago your group showed that dopamine does cause uterine artery vasoconstriction and could be a vehicle for this cocaine-induced effect.[1] Have you followed up that study with dopamine blockers to evaluate that issue further?

The second question really relates to the issue of cocaine and pregnancy itself. We know in the sheep that cocaine produces almost a twofold greater cardiovascular response in pregnancy than it does in the nonpregnant state.[2] Moreover, we now know that progesterone seems to be the vehicle that is mediating this unusual drug reaction. In fact, we can reproduce this in the nonpregnant state if one gives progesterone and then gives cocaine.[3]

Have you duplicated any of your infusions either after these pregnant baboons are delivered of infants or more specifically, in the nonpregnant state to compare cocaine-induced cardiovascular effects in pregnant versus nonpregnant baboons?

Dr. James C. Warren, St. Louis, Missouri. I have one question. I would like some hard data on how your dosages really compare with human users in terms of milligram per kilogram of body weight. I assume they are in the range, but I would like some better information on that, please.

Dr. Morgan (Closing). To answer Dr. Resnik's first question as to the reliability of our observations, I think that any time an investigation is initially performed it needs to be duplicated, either by ourselves with different dosages or by other investigators in a similar animal model. Until that occurs, we really will not know what is truth. We did observe statistical significance with the paired Student *t* test. This statistical test is the most stringent that is used for these particular types of observations.

As to the question, "what is the mechanism of action for the continued uterine blood flow reduction that occurs after blockade of the α_1-adrenergic receptors?" there are two mechanisms that can be related or can be interacting. There are both extrinsic and intrinsic resistances that affect uterine blood flow. What has been specifically investigated with the α_1-adrenergic blockade is the intrinsic resistance, specifically blocking the effects of norepinephrine on the uterine vasculature.

At this meeting in 1987 Dr. Fishburne[1] showed that regional dopamine infusions into the common iliac artery of pregnant baboons caused profound reductions in uterine blood flow. The likely dopamine-mediated increase in intrinsic resistance is also a probable cause for the reduction in uterine blood flow after cocaine administration.

Another possible mechanism is that cocaine could exert a direct effect on the uterine vasculature. Other local anesthetic agents such as lidocaine, administered as a paracervical block, have resulted in profound fetal bradycardia.[2] These observations could be a result of intrinsic vasoconstriction of the uterine vasculature caused by the local anesthetic agents.[3,4]

Increased extrinsic resistance, uterine contractility, could be related to the pharmacologic effects of cocaine. Dr. Griess[5] in 1972 observed that a systemic infusion of norepinephrine caused an increase in uterine activity as measured by intrauterine pressure catheter. This uterine contractile response was somewhat blocked by the administration of phenoxybenzamine in various doses. As to the effect of norepinephrine on the baboon's uterine contractility, the α_1-adrenergic receptor blockade of that effect remains to be determined.

We observed with these cocaine dosages and three others (0.5, 1.0, and 2.0 mg/kg), measuring uterine contractility with intrauterine pressure catheters and electromyographic electrodes, that there is a profound dose-mediated effect on uterine contractility in the nonhuman primate. This effect of cocaine needs to be explored as another possible mechanism for the reduction in uterine blood flow.

As to Dr. Caritis' question on the measurement of intrauterine pressure. The uterine activity did increase and appeared to be related to the dose used. Unfortunately, we did not have the prostaglandin assays finished in time for this particular report.

Observations were obtained over 30 minutes because of study design. However, for the other cocaine doses that I mentioned (0.5, 1.0, and 2.0 mg/kg) we collected data out to 60 minutes and saw similar though greater effects as those observed in this study.

With relation to the state of the animals, each baboon was in her normal upright posture, as in the gang cages. The only difference is that they were wearing a jacket attached to a tether, allowing them freedom to move around in the cage.

The reaction to the cocaine was different from animal to animal. After the higher doses, two of the animals showed twitching of the ears and enlargement of the pupils. However, one observation present in all the baboons was that their buttocks became more intensely red with the increase in the dosage of cocaine. I do not know why this occurs.

To answer Dr. Woods' questions, we are currently preparing to undertake studies that involve dopamine blockade and nonpregnant baboon cocaine infusion studies.

Last, Dr. Warren asked whether the cocaine doses we used in this study are similar to those used by cocaine abusers. We have not obtained these data. The only data that I am aware of are that of Moore et al.[6] who stated that the cocaine blood levels they obtained in their study were similar to peak levels obtained in male volunteers. We have frozen blood samples from which to obtain cocaine levels; however, these assays have not been performed.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1991 issues from the Publisher, at a cost of $61.00 for domestic, $88.27 for Canadian, and $84.00 for international for Vol. 164 (January-June) and Vol. 165 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

c-*myc* Protooncogene polypeptide expression in endometriosis

Robert S. Schenken, MD, Julia V. Johnson, MD, and Robert M. Riehl, PhD

San Antonio, Texas

The c-*myc* protooncogene and its polypeptide product are important regulators of cell proliferation and differentiation, and ovarian steroids are believed to stimulate growth of various uterine cell types through altered expression of the c-*myc* gene. To determine whether c-*myc* expression may also be involved in the growth and development of endometriosis, we assessed c-*myc* expression in eutopic and ectopic endometrial tissue obtained from women undergoing surgery for endometriosis. Immunocytochemistry using a monoclonal antibody to the c-*myc* protein demonstrated positive staining of glandular and stromal cell nuclei, and cytoplasmic staining of glandular but not stromal cells in both eutopic and ectopic endometrium. These findings suggest that c-*myc* expression may be an important regulator of cell proliferation in endometriotic tissue. (AM J OBSTET GYNECOL 1991;164:1031-7.)

Key words: Endometriosis, c-*myc* protooncogene, c-*myc* polypeptide, immunocytochemistry

Factors regulating the development, growth, and differentiation of endometriosis are poorly understood. Studies to date have suggested that ovarian steroids and estrogen, in particular, serve as the primary mitogenic stimulus for endometriotic tissue.[1] Evidence supporting this includes the clinical observations that endometriosis regresses in hypoestrogenic states,[2, 3] the stimulation of ectopic endometrial growth in animal models treated with exogenous steroid,[3, 4] and the demonstration of both estrogen and progesterone receptors in endometriotic tissue.[5-7] However, these studies also have shown that endometriotic tissue is markedly heterogeneous in its response to ovarian steroids and in its steroid receptor content. For example, ectopic endometrium rarely follows the orderly morphologic changes that occur in eutopic endometrium during the menstrual cycle.[8] In pregnancy, where circulating estrogen and progesterone levels are elevated, most endometriotic implants regress, but some remain unchanged and others may actually increase in size.[9] Although estrogen and progesterone receptors are present in most endometriosis specimens, the concentration of receptor is usually lower than that in eutopic endometrium and several endometriotic implants have no steroid receptors.[5-7] These observations suggest that although ovarian steroids stimulate endometrial cell growth, additional mechanisms, must be involved in controlling endometriotic cellular proliferation.

Recent studies have demonstrated that vertebrate cells contain a number of genes that encode for proteins that are involved in the regulation of cell division and differentiation.[10] These genes are known as protooncogenes because of their similarity to viral oncogenes that are present in the genome of many tumor cells and induce unrestrained cell growth. That the c-*myc* gene, a cellular homologue of the viral v-*myc* oncogene, is a highly conserved gene suggests that it serves a critical function.[11] The gene encodes a nuclear protein that has been positively correlated with cellular proliferation and deoxyribonucleic acid (DNA) synthesis and inversely correlated with cellular differentiation. Although the exact structure and function of the c-*myc*–encoded protein are unknown, it has been postulated that ovarian steroids induce proliferation and differentiation of various cell types via expression of the c-*myc* gene.[12, 13] Accordingly, we questioned whether the c-*myc* gene was also a potential regulator of cell growth in endometriotic tissue and herein report the first immunocytochemical demonstration of the c-*myc*–encoded polypeptide in endometriosis.

Material and methods

Eutopic and ectopic endometrial tissue was obtained from 15 women undergoing laparoscopy or laparotomy for evaluation of infertility or the treatment of pelvic endometriosis. All patients underwent surgery during the proliferative phase of the menstrual cycle. Five patients had ovarian endometriomas and 10 had peritoneal endometriotic implants. Patients ranged from 28 to 40 years of age and none had received recent hormonal therapy.

Histomorphology. Tissue specimens were fixed in 10% formalin and embedded in paraffin. Tissue sections (4 μm) were stained with hematoxylin and eosin for routine histologic examination. All eutopic endometrial specimens were dated according to the criteria of Noyes et al.[14]

From the Division of Reproductive Endocrinology and Infertility, Department of Obstetrics and Gynecology, The University of Texas Health Science Center at San Antonio.

Presented at the Ninth Annual Meeting of the American Gynecological and Obstetrical Society, Hot Springs, Virginia, September 6-9, 1990.

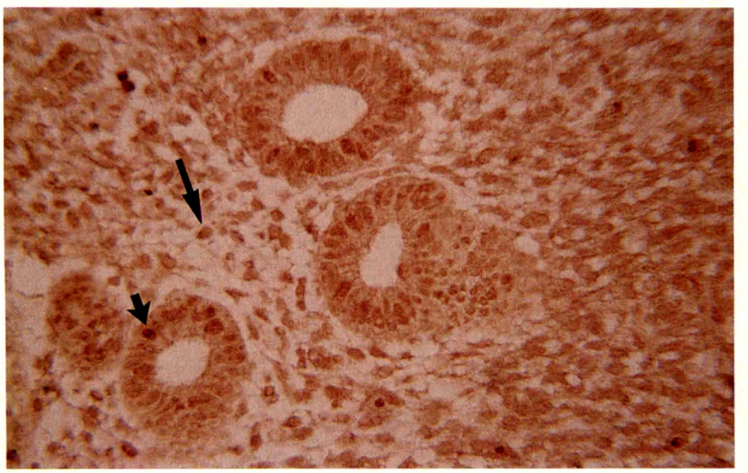

Fig. 2. Immunocytochemical localization of c-*myc* polypeptide in eutopic endometrium section shown in Fig. 1. Formalin-fixed, paraffin-embedded section was incubated with monoclonal antibody to c-*myc* p62 and stained by the peroxidase-antiperoxidase method. Glandular cell nuclei *(small arrow)* demonstrated intense staining with relatively weaker staining of the cytoplasm. In stromal cells only nuclear staining was apparent *(large arrow)*. (Original magnification ×400.)

Immunocytochemistry. Tissue sections were deparaffinized in xylene and rehydrated in decreasing concentrations of ethanol. Rehydrated sections were pretreated with 3% hydrogen peroxide in methanol to block endogenous peroxidase activity and then 4% goat serum to reduce nonspecific background. The primary antibody (obtained from Oncogene Science, Inc., Manhasset, N.Y.) was produced by immunizing BALB/c mice with the amino acid sequence 408 through 439 of the c-*myc*–encoded 62 kd molecular weight protein (c-*myc* p62) and fusion of SP2 mouse myeloma cells. Sections were incubated with this monoclonal primary antibody at a 1:20 dilution in phosphate-buffered saline solution for 18 hours at room temperature. Immunocytochemical localization was performed using the Vectastain ABC-peroxidase kit (Vector Laboratories, Inc., Burlingame, Calif.) for mouse primary antibody, which uses a biotinylated second antibody, horseradish peroxidase–streptavidin conjugate, and the substrate chromogen diaminobenzidine. Controls consisted of tissue sections incubated with normal mouse serum in the absence of primary antibody. All slides were mounted and examined under bright field.

Results

Histologic dating of eutopic endometrium demonstrated endometrium from the early and mid proliferative phase. Endometrial glands and stroma were present in all endometriotic tissue specimens, but suf-

Islands of positively stained stromal nuclei are occasionally present. (Original magnification ×100.)

ficient glandular-stromal architecture to assign dates of the tissue was present in eight specimens. In each case, eutopic and ectopic endometrial specimens were assessed as being early or mid proliferate.

Eutopic endometrial tissue stained positive for c-*myc* p62. Both nuclear and cytoplasmic staining were consistently present in endometrial glands, with nuclear staining being predominant. Nuclei of stromal cells also stained positive, but no cytoplasmic staining was apparent (Figs. 1 and 2). No staining was observed in eutopic endometrium incubated in the absence of primary antibody.

Ectopic endometrial tissue glands in peritoneal implants demonstrated nuclear and occasional cytoplasmic staining (Figs. 3 and 4). Epithelium lining the cyst wall and endometrial glands adjacent to the cyst wall of endometriomas also showed nuclear and occasional cytoplasmic staining (Figs. 5 and 6). In contrast to eutopic endometrial tissue, the intensity of staining in the nuclei and cytoplasm of glandular epithelium in ectopic endometrium was markedly variable. When cytoplasmic staining was present, most sections demonstrated it to be of less intensity than nuclear staining, but some fields showed an equivalent intensity of cytoplasmic and

nuclear staining. No staining was observed in ectopic endometrial tissue incubated in the absence of primary antibody.

Comment

The aim of this study was to determine whether c-*myc* p62 was present in endometriosis and to obtain preliminary information on qualitative difference in c-*myc* expression in eutopic and ectopic endometrium. Using immunocytochemistry, c-*myc* p62 was identified in the nuclei and cytoplasm of glandular epithelial cells and in the nuclei of stromal cells. Similar findings were observed in eutopic endometrium. When eutopic and ectopic endometrial staining was compared in individual patients, ectopic specimens demonstrated less intense nuclear and cytoplasmic staining and a greater variability in staining among individual glands. We are unaware of any studies that have assessed c-*myc* expression in endometriosis. However, our findings in eutopic endometrium are consistent with one previous report describing changes in endometrial c-*myc* expression during the menstrual cycle.[16] In that study, nuclear staining predominated over cytoplasmic staining in glands obtained during the proliferative phase, but the

converse was observed in secretory endometrium. These findings are consistent with the observation of a nuclear distribution of c-*myc* p62 in actively dividing cells (such as proliferative endometrium) and a cytoplasmic distribution in normal or terminally differentiated cells (such as secretory endometrium).[17] In our study, specimens were obtained only during the proliferative phase. Consequently, it remains to be established whether ectopic endometrium exhibits changes in c-*myc* p62 nuclear-cytoplasmic distribution during the menstrual cycle.

The c-*myc*–encoded protein runs as a doublet with approximate molecular weights of 62 and 64 kd or 64 and 66 kd.[18, 19] The half-life of c-*myc* p62 is very short (20 to 30 minutes), which is consistent for a gene with a role in the regulation of cell proliferation.[19] Although c-*myc* p62 is believed to be primarily a nuclear protein, our immunocytochemistry findings indicate that the protein also is present in the cytoplasm of ectopic endometrial glandular epithelium. Because the catabolism of the c-*myc* protein is unknown, the positive staining of the endometrial epithelial cytoplasm may represent either cytoplasmic synthesis of the protein or a cleavage product of native c-*myc* p62 that was recognized by the monoclonal antibody employed. Western protein blot studies of endometriosis are in progress to investigate the possibility of antibody recognition of its epitope in proteins with lower molecular weights than c-*myc* p62.

Identification of the c-*myc* polypeptide product in endometriosis is an important first step in understanding the role of c-*myc* expression in regulating the development and growth of endometriotic implants. Numerous studies have indicated that the c-*myc* protooncogene and its encoded protein are major components in the regulation of cell proliferation and differentiation.[20] A rapid increase in c-*myc* protooncogene expression is seen after mitogen stimulation of cells, and this c-*myc* induction is associated with transition of cells from a quiescent G_0 state to G_1.[20] Transfection of the c-*myc* gene or microinjection of the c-*myc* protein also will commit quiescent cells to enter the cell cycle.[21, 22] Although the specific function of the c-*myc*–encoded protein is unclear, isolated c-*myc* p62 binds DNA in vitro and may also bind to the nonchromatin structure, termed the nuclear matrix, which is the postulated site of DNA synthesis.[23] Monoclonal antibodies to c-*myc* p62 will reversibly inhibit DNA synthesis and DNA polymerase, further suggesting that the c-*myc*–encoded protein participates in DNA and cell replication.[24] These studies and our demonstration of c-*myc* expression in endometriosis suggest that c-*myc* also is important in regulating transcriptional mechanisms associated with the mitotic cycle of endometriotic cells.

It has been proposed that ovarian steroids mediate eutopic endometrial cell proliferation and differentiation though altered expression of the c-*myc* gene. In oophorectomized mice, estradiol administration rapidly increases c-*myc* messenger ribonucleic acid; this increase is followed by c-*myc* protein accumulation and DNA synthesis in endometrial glandular epithelial cells.[12] Progesterone has similar effects in stromal cells, but blocks estradiol-induced c-*myc* expression in epithelial cells. In vivo treatment with estradiol also induces rapid accumulation of c-*myc* messenger ribonucleic acid in uteri of oophorectomized rats.[13] These studies did not determine whether c-*myc* expression was a direct effect of estradiol or was mediated through hormonally induced paracrine growth factors. The latter possibility is of importance because estradiol increases messenger ribonucleic acid levels of epidermal growth factors and biosynthesis of epidermal growth factor receptors in uterine cell cultures; in some tissues epidermal growth factor induces c-*myc* expression.[12, 25] These findings suggest that endometrial cell growth is regulated by a complex interaction between ovarian steroids and growth factors, with the c-*myc* protooncogene acting as a common mediator of these mitogenic signals.

We appreciate the support of Dr. Calvin C. Hayslip for providing the endometriosis tissue specimens and gratefully acknowledge the assistance of Alice Schmitter in the preparation of this manuscript.

Discussion

DR. ROGER D. KEMPERS, Rochester, Minnesota. The c-*myc* protooncogene is expressed in all eukaryotic tissue studied to date, including the growing embryo, the endometrium, and malignant cells. There have been few studies of c-*myc* expression on endometrial samples. Notable have been those by the groups headed by Odom et al. at the Medical College of Georgia (see ref. 16 of article) and Stradtman at the University of Alabama. I am indebted for their counsel in preparing this discussion and also to the reknowned pathologist, Dr. Hazel Gore, for her interpretation of the photomicrographs. Dr. Schenken and his associates have established themselves in this field with the first study of c-*myc* expression in endometriotic tissue. This is a novel study for which they are to be commended.

However, some clarifications and revisions are necessary to make this report more convincing. Permit me to detail several concerns with this study and try to be constructive.

First of all, there is a critical need in the study design for both good positive and good negative tissue controls. The authors studied eight histologic endometriotic sections and an unspecified number of normal endometrial samples. They did not use a negative control other than a negative control for technique by eliminating the antibody. Indeed, it is difficult to obtain negative controls for c-*myc* expression, but germinal centers in the spleen are one of the tissues that do not express this protooncogene. The data from the negative controls for technique cannot be interpreted because the authors did not include their negative control photomicrographs, prepared without antibody. Conclusions regarding positive cytoplasmic staining are not at all conclusive without the control stains for evaluation of background staining. There is a lack of positive control for the histologic or immunohistologic studies other than the use of normal endometrium. Positive control tissue that could be used would be cells from Burkitt's lymphoma, where large quantities of c-*myc* are present or cells from histiocytosis X in the spleen.

The second problem is the lack of evidence of quantitative differences of c-*myc* expression, which was a stated goal. Quantitative analysis of the data by counting the number of grains in the field or performing computerized video imaging was not done. Semiquantitation of the data would strengthen the merits of the study because differential expression in different samples may have important biologic implications.

The third concern relates to several inconsistencies in the interpretation of the photomicrographs of the histologic samples submitted. Fig. 1, which was reported as proliferative endometrium, contains tubular glands, subnuclear vacuoles, and rather edematous stroma; glandular mitoses are not detectable. These findings are not as consistent with early or mid proliferative endometrium as they are with anovulation, a prolonged proliferative phase, or even an early postovulatory state. In Figs. 3 and 4 the large arrows are stated to indicate deep glands, which are not represented in the corresponding hematoxylin and eosin sections. These structures are suggestive of blood vessels and are thus ambiguous. Although the epithelial nuclear staining denoted by the small arrow seems valid, it is curious that such a limited area was selected when more intact glands of epithelium are present in the field. The cells indicated by the large arrows in Figs. 5 and 6 are stated to be stromal cells but could be confused with lymphocytes.

Related to this is a fourth concern. There is a lack of convincing evidence that all of these patients underwent surgery in the proliferative phase of the cycle. The indications for surgery are not given and information about their menstrual histories is limited. Ac-

curate menstrual data should have been obtained at the time of surgery to correlate with the histologic findings. Although the report states that these patients had no recent hormonal therapy, the authors should also provide the minimal time interval since the last such therapy. Since c-*myc* is expressed in mitotically active tissue, positive staining in anovulatory endometrium would not necessarily invalidate the authors' hypothesis. However, the conclusions do pertain to proliferative phase endometrium, and more conclusive evidence should be provided to confirm that normal proliferative endometrium was examined.

Finally, the authors should rewrite two of their conclusions, which are substantiated by the literature but not by their data. Their data show only that c-*myc* protein is expressed in the tissues, appears to take an intranuclear location, and may leak into the cytoplasma. The mere expression of a protein does not support any mediation or regulation. Any direct involvement in regulation of steroid action, by steroids, or as a mediator is only speculation, and this should be clearly stated.

I enjoyed reading this interesting report and hope that the authors will be willing to revise and thus strengthen their manuscript by addressing these concerns about controls, quantitation of the data, photomicrograph interpretation, relevant clinical findings, and appropriateness of conclusions. I look forward to forthcoming contributions in this field by this fine research team.

Dr. Roland A. Pattillo, Milwaukee, Wisconsin. I have one simple question: Would you speculate on the basis for expression of the c-*myc* oncogene protein product in stromal cell in stromal nuclei but not in stromal cell cytoplasm? Is there a significance that is implied from differential expression in the nucleus alone? Is this significance related to the degree of fibrotic reaction to endometrial implants?

Dr. James Schreiber, Chicago, Illinois. You observed a correlation with proliferation, and I wonder whether you have performed this study on luteal phase endometrium just to see if there is a difference in the expression of c-*myc* between what is found in the proliferative phase and in the luteal phase.

Dr. George D. Wilbanks, Chicago, Illinois. I have a similar question, in regard to hyperplasia or tumors of the endometrium.

Dr. Schenken (Closing). I will start with the last question and then address Dr. Kempers' concerns. We have not personally done any studies on c-*myc* expression in endometrial hyperplasia or carcinoma. Other studies have demonstrated that the c-*myc* protooncogene and other cellular oncogenes are expressed in endometrial neoplasia.[1-4]

In the luteal phase overall cellular staining for c-*myc* is somewhat less intense. In the luteal phase epithelial cells, the cytoplasmic staining is somewhat greater than that observed during the proliferative phase. This is probably related to the terminal differentiation of these cells, where the protein is transported from the nucleus into the cytoplasm. In stromal cells only nuclear staining is observed because these cells continue to proliferate throughout the menstrual cycle.

In regard to Dr. Kempers' questions on the indications for surgery, all of these patients were undergoing diagnostic laparoscopy within 10 days of the last menstrual period. All patients were ovulatory as assessed by routine studies: serum progesterone level, endometrial biopsy, menstrual history, etc.

Dr. Kempers questioned the certainty of staining of the glandular components of the ectopic endometrial tissue. In rare cases, we observed staining of blood vessels; these were clearly vessels because red blood cells were present in the luteum. In some cases it is difficult to distinguish between vessels and atrophic glands because the endometrial glandular-stromal architecture is not always as precise as it is in the eutopic endometrium. Even in atrophic or misshapen glands, the absence of endothelial cells and red blood cells in the lumen suggests that these structures are endometrial glands.

We are working on a technique to quantitate c-*myc* expression by computer analysis. This has proved difficult because the endometriotic tissue is heterogeneous and not every microscopic field contains sufficient endometrial glands and stroma.

I appreciate the suggestions regarding the positive and negative controls. In one study the positive control was the staining of eutopic endometrium, which has been demonstrated previously. The negative control was the lack of staining of sections incubated in the absence of primary antibody. It is true that the c-*myc* protooncogene is expressed in almost all tissues to date; we were interested in whether c-*myc* protooncogene was present in this estrogen-sensitive tissue and its potential role in cell proliferation.

It is currently unclear whether the c-*myc* protooncogene is a critical regulator of cell proliferation in endometriosis. We are developing studies to look at this in explanted cultures of human endometrium and in a rat model. On the basis of previous studies of eutopic endometrium in rats, we believe that c-*myc* expression will be demonstrated to be an important regulator of endometriotic tissue growth.

Serum interleukin-6 levels correlate with disease status in patients with epithelial ovarian cancer

Jonathan S. Berek, MD, Catherine Chung, BS, Klara Kaldi, BS, Joanna M. Watson, BSc, Reba M. Knox, MS, and Otoniel Martínez-Maza, PhD

Los Angeles, California

Interleukin-6 is a pleiotropic cytokine with a wide range of effects, including induction of B-cell and cytotoxic T-cell differentiation, and induction of acute phase reactant production by hepatocytes. Interleukin-6 also can act as an autocrine growth factor in malignancy. Various cell types produce interleukin-6, including T and B cells, monocytes, fibroblasts, and some solid tumor cells. In previous work we detected the production of substantial amounts of interleukin-6 by human ovarian cancer cells, including the ovarian cancer cell lines CAOV-3, OVCAR-3, and SKOV-3, and several primary ovarian tumor cultures. In this study we retrospectively examined 90 separate serum specimens for interleukin-6 in 36 patients with epithelial ovarian cancer. The mean serum interleukin-6 concentration of those ovarian cancer patients with macroscopic disease ($n = 57$) was 0.26 ± 0.04 U/ml (mean ± SEM). Healthy adult donors have interleukin-6 serum levels of 0.12 ± 0.03 U/ml. Sixteen of 21 ovarian cancer patients with macroscopic disease (76%) had elevated (>0.20 U/ml) levels of serum interleukin-6, with levels approaching 1 U/ml in some patients ($p < 0.01$). Of those nine patients with bulky tumor (residual >2 cm), eight (89%) had an elevated interleukin-6 level (mean, 0.31 ± 0.05), while eight of 12 (66%) with minimal residual disease (<2 cm) had elevated levels. Only two of 15 (13%) patients who were in clinical remission and who had microscopic disease had elevated values. Of the 36 patients, 22 were CA 125 negative (<35 U/ml), and of these, four had elevated interleukin-6 levels. Of the 14 patients with an elevated CA 125 level, 12 (86%) had elevated interleukin-6 levels. In those 16 patients in whom serial levels of interleukin-6 were measured, rising levels were found over a 3 to 4 month interval in nine (56%); this correlated with tumor progression. Furthermore, the subsequent survival of patients was shown to correlate with the level of interleukin-6, such that patients whose levels were elevated >0.20 U/ml interleukin-6 survived a mean of 12.5 months, compared with 27.2 months for patients with normal levels ($p < 0.001$). These data support the concept that interleukin-6 may be a useful tumor marker in some patients with epithelial ovarian cancer, as it correlates with the tumor burden, clinical disease status, and survival. (Am J Obstet Gynecol 1991;164:1038-43.)

Key words: Human ovarian cancer, cytokines, interleukin-6, serum levels

Of all gynecologic malignancies, ovarian cancer has the lowest overall survival rate. Most patients have advanced stage disease at the time of diagnosis.[1] Monitoring and detection of subclinical disease is limited because the majority of diagnosed patients have no measurable disease while they are undergoing treatment. Therefore suitable biomarkers are needed. The ovarian cancer–associated marker, CA 125, has been the most well characterized, and it has been useful in helping to monitor the course of disease in many patients with nonmucinous epithelial malignancies.[2] Also, ovarian malignancies frequently metastasize throughout the peritoneal cavity before the development of symptoms,[1] and thus better methods of early detection are needed.

Interleukin-6 (IL-6), also known as BSF-2, interferon beta-2, hybridoma/plasmacytoma growth factor, and 26 kd protein,[3-6] is a pleiotropic cytokine involved in numerous, diverse biologic functions.[7-9] IL-6 has been shown to be produced by human tumor cells including cardiac myxoma cells,[10] myeloma cells,[11] and acquired immunodeficiency syndrome–associated Kaposi's sarcoma cells.[12] IL-6 can augment the growth of myeloma cells or Kaposi's sarcoma cells in an autocrine loop.[11, 12] Recent evidence has shown that IL-6 is produced by both human epidermal cells and epidermoid carcinoma

cell lines[13] as well as other epithelial tumors including bladder carcinoma cells[14] and renal cell carcinoma.[15] Because the majority of ovarian carcinomas arise from the coelomic epithelium that covers the ovarian surface,[1] we examined the production of IL-6 from several established ovarian carcinoma cell lines and from freshly excised epithelial ovarian tumors.[16] We showed that three of four established ovarian carcinoma cell lines, as well as primary cultures taken from ovarian tumors, secrete IL-6. By all criteria examined, this IL-6 was indistinguishable from that produced by other epithelial, lymphoid, or monocytoid cell lines. Furthermore, these epithelial ovarian tumor cell lines may produce IL-6 as an autocrine growth factor.

Recent data have shown that ovarian stroma and follicles are rich in IL-6 gene expression; this appears to be related to angiogenesis.[17] Thus IL-6 may function as a paracrine growth factor in the normal ovary. In tumorigenesis, the proliferation of new blood vessels is a critical step,[18] and therefore the overexpression of IL-6 might serve as an internal promoter of neoplasia in a manner that helps to support the growth of the tumor. With the proliferative activity, IL-6 might be secreted in large quantities into the peritoneal cavity and then into the systemic circulation.

Tumor development has been associated with either oncogene expression and amplification or inappropriate growth factor regulation.[19-21] There has been little success in correlating significant oncogene expression and amplification with ovarian cancer,[20] with the exception of the recently identified HER-2/*neu* oncogene,[19] which encodes an epidermal growth factor–like receptor,[21] has been found to be overexpressed in approximately 30% of ovarian malignancies, and correlates with a poor clinical prognosis. These findings support the concept that the development and progression of ovarian cancer may be related to inappropriate growth factor regulation. IL-6 is a growth factor that offers potential relevance to the understanding of ovarian malignancies.

On the basis of this rationale, we sought to characterize the production of this cytokine by ovarian tumors and to provide information on the role of IL-6 as a growth factor for ovarian cancer. The preliminary finding of elevated levels of circulating IL-6 in the serum of patients with epithelial ovarian cancer stimulated our efforts to correlate the patients' tumor status with the levels. These data might provide a new serum marker that can be used for the diagnosis and treatment of ovarian carcinoma.

Material and methods

Patients. Patients with histologically documented epithelial ovarian cancer were studied. Blood was drawn at the time of either hospital admission for surgery or therapy, or at outpatient visits. In all cases the physical examination was performed by a physician and the status recorded in the chart. Serial evaluations permitted the determination of whether the patient was in clinical remission or whether measurable disease was progressing, regressing, or stable. When available, radiographic evidence of disease by computed tomographic scan was monitored by repeat scans. The extent of residual disease was measured by laparotomy and was quantitated by the surgeon. Survival of patients was measured in months from the time of surgery to latest time of follow-up or death.

Serum samples. Aliquots of blood were obtained by venipuncture in 15 ml siliconized glass tubes without coagulants. The blood was allowed to clot and centrifuged at 1000 rpm for 10 minutes; then the separated serum was removed. Serum specimens were assayed immediately or stored at −70° C, thawed, and assayed. We have found that a single freeze-thaw does not affect the levels of measurable IL-6. The specimens were handled consistently and processed rapidly to avoid spurious production of IL-6 by the patients' leukocytes.

IL-6 assay. Serum specimens were determined to have IL-6 biologic activity by bioassay using the IL-6 dependent murine hybridoma cell line MH60.BSF-2 (kindly provided by Dr. T. Kishimoto and Dr. T. Hirano, Osaka, Japan) as previously described.[16, 22] Briefly, MH60.BSF2 cells are maintained in RPMI-1640 medium supplemented with 10% fetal calf serum, 1% antibiotics, 1% glutamine, 2% 2-mercaptoethanol, and 5 U/ml recombinant human IL-6 (rhIL-6, provided by Dr. T. Kishimoto). Duplicate serum samples were serially diluted in 96-well flat bottom plates (Nunc, Inc., Roskilde, Denmark). A total of 1×10^4 washed MH60.BSF2 cells was added per well, and the plates were incubated at 37° C for 42 hours. The cells were pulsed with 1 μCi ^{3}H-thymidine (ICN Biochemicals, Irvine, Calif.) for 6 hours and harvested onto glass membrane filters; then the radioactivity was counted.[15] IL-6 levels were determined by comparison with MH60.BSF2 cell proliferation induced by samples that have been exposed to known quantities of rhIL-6. We have shown that the addition of anti-IL-6 antibody eliminates IL-6–induced IL-6/MH60.BSF-2 cell proliferation.[16] Serum specimens were heat treated (56° C, 30 minutes) to remove nonspecific IL-6 inhibitory activity.[23] Interassay variation was assessed, and the mean variation was 20%. The assay was performed by laboratory personnel unfamiliar with the clinical status of the patients.

CA 125 assay. CA 125 was measured in the serum using the standard radioimmunometric assay with a murine monoclonal antibody (OC 125) and measured in a γ-scintillation counter using duplicate specimens.[24]

Statistics. Statistical analysis was done by using Student's *t* test.

Table I. IL-6 serum levels by bioassay in patients with epithelial ovarian cancer

Disease status	*Patients (No.)*	*Specimens (No.)*	*IL-6 levels Elevated**	*Mean ± SEM*
Macroscopic	21	57	16 (76%)	0.26 ± 0.04†
Bulky (>2 cm)	9	27	8 (89%)	0.31 ± 0.05‡
Minimal residual disease (<2 cm)	12	30	8 (67%)	0.23 ± 0.04†
Microscopic	15	33	2 (13%)	0.09 ± 0.03
TOTAL	36	90	18 (50%)	0.24 ± 0.04†
Control	12	12	2	0.12 ± 0.03

*Sensitivity (macroscopic), 0.76; microscopic plus macroscopic, 0.50.

†$p < 0.05$, versus control.

‡$p < 0.01$, versus control.

Table II. Correlation of serum IL-6 levels and CA-125 levels in patients with epithelial ovarian cancer

CA 125 level	*No. of patients*	*Elevated IL-6 level*
Normal (<35 U/ml)	22	4 (18%)
Elevated (>35 U/ml)	14	12 (86%)

Correlation coefficient = 0.84.

Results

The IL-6 levels of bioassay from 36 patients with epithelial ovarian cancer are presented in Table I. IL-6 levels in 90 separate serum specimens were measured. The mean values of the initial levels are correlated with the extent of disease at the time of exploratory laparotomy. The mean serum level of those ovarian cancer patients with macroscopic disease ($n = 57$) was 0.26 U/ml. Sixteen of 21 patients (76%) in this group had elevated levels of serum IL-6 (>0.20 U/ml), with serum levels approaching 1 U/ml in some patients. On the basis of the IL-6 value of 0.12 ± 0.03 U/ml in the serum of healthy adult female volunteer donors tested ($n = 12$), the values in cancer patients are elevated significantly.

Of the nine patients with bulky tumor (residual >2 cm maximum tumor dimension), eight (89%) had an elevated IL-6 level (mean, 0.31) ($p < 0.01$), whereas eight of 12 (66%) with minimal residual disease (<2 cm maximum tumor dimension) had elevated levels ($p < 0.05$). Only two of 15 (13%) patients who were in clinical remission and who had microscopic disease had elevated serum values.

CA 125 levels were correlated with IL-6 levels. Of the 36 patients, 22 were CA 125–negative (<35 U/ml), and of these, four had elevated IL-6 levels. Of the 14 patients with elevated CA 125 levels, 12 (86%) had elevated interleukin-6 levels (Table II). Fifteen of the 36 patients tested had microscopic disease only at the time of measurement, and all but one of these patients had a negative CA 125 level.

Serial IL-6 levels were measured in 16 patients. Rising serum levels were found over a 3 to 4 month interval in nine patients (56%), and in all cases this correlated with tumor prognosis. Of the other seven serial levels, five remained within the same range and two decreased; these patients had subclinical disease and remained in clinical remission during this interval.

Patient survival was correlated with levels of IL-6 at the time of laparotomy. Subsequent survival of patients was shown to correlate with the initial level of IL-6, so that patients whose levels were elevated >0.20 U/ml survived a mean of 12.5 months, compared with 27.2 months for those patients with normal levels ($p < 0.001$).

Comment

Our study shows that the serum of many patients with epithelial ovarian cancer contains levels of the growth and differentiation factor IL-6 that are significantly higher than those found in normal controls. The levels correlate with the extent of residual disease, such that those patients who have a large tumor burden also tend to have high IL-6 serum levels. Furthermore, in patients who develop evidence of clinical progression, the IL-6 levels become elevated. The survival of patients from the time of surgery correlates with the level of elevation, suggesting that overexpression of this growth factor might be prognostic in epithelial ovarian cancer. Thus these data suggest that serum IL-6 measurements may be a useful biomarker for epithelial ovarian cancer.

Ovarian malignancies constitutively produce IL-6. We have reported previously that most epithelial ovarian cancers studied in vitro produce significant levels (>10 ng/ml) in the supernatants of primary ovarian tumor cultures.[16] Tabibzadeh et al.[25] examined IL-6 immunoreactivity in human tumors by immunohistologic staining and found that the majority of human tumors of epithelial or mesenchymal origin stain positive. Furthermore, three well-characterized human epithelial ovarian carcinoma cell lines, CAOV-3, NIH-OVCAR-3, and SKOV-3, constitutively produce biologically active and antigenically related IL-6.[16] The IL-6 produced by these ovarian cancer cell lines has a molecular weight of approximately 24 kd, and exhibits some of the molecular weight heterogeneity often associated with IL-6 produced by nonovarian epithelial cells.[13, 16] All of the primary ovarian tumors and ovarian cell lines that produce IL-6 activity are epithelial adenocarcinomas,

and the only ovarian carcinoma cell line tested that does not produce any IL-6, PA-1, was originally derived from a teratocarcinoma,[26] a germ cell tumor.

The secretion of IL-6 into the blood of patients with epithelial ovarian cancer is presumably based on the up-regulated expression of the IL-6 gene within the ovarian epithelial and stromal cells of these malignancies. A recent report by Motro et al.[17] suggests that IL-6 is a paracrine growth factor secreted by the epithelial and stromal cells of normal ovaries and by the ovarian follicles and that IL-6 gene expression is associated with angiogenesis within the stroma. On the basis of these data, we postulate that, during the process of tumorigenesis, IL-6 gene expression helps to promote tumor growth and excess IL-6 is secreted into the peritoneal cavity and blood of the patient.

Although IL-6 has been implicated as an autocrine growth factor in other tumor systems,[11, 12, 15] we have reported that added exogenous IL-6 does not lead uniformly to the increased proliferation of ovarian cancer cells and that anti–IL-6 serum does not inhibit ovarian tumor cell growth.[16] The lack of proliferative response to exogenous IL-6 suggests that these ovarian carcinoma cell lines are not producing this cytokine as an extracellular autocrine growth factor.[16] However, the possible role of ovarian cell–produced IL-6 as an intracellular autocrine growth factor for ovarian cancer cells or as an exocrine or paracrine growth factor for other cells of the peritoneal cavity is interesting, because of the high levels of the cytokine that are produced and retained within the peritoneum and the lack of metastasis outside of the cavity. It has been proposed by Tamm et al.[27] that IL-6 may promote tumor metastasis and invasiveness because exogenous IL-6 has been shown to increase motility and decrease adherens junctions in the breast carcinoma cell lines T47D and Zr-75-1. It is not known whether autonomously produced IL-6 would affect the motility and adherence of the ovarian cancer cell lines, but this phenomenon could explain the extensive peritoneal carcinomatosis seen in patients with ovarian carcinoma. Also, IL-6 could play an important role in the establishment of autonomous tumor by acting as an angiogenesis-inducing factor.[17]

We have previously reported that there are extremely high levels of this cytokine within the peritoneal cavity ascitic fluid of patients with ovarian cancer.[16] The high concentrations of IL-6 within a confined and localized region reported here are not unique, as high levels (>1000 U) have been reported to be present in amniotic fluid,[28] in the synovial fluid of rheumatoid arthritis patients,[29] and in localized regions of acute bacterial infections.[30] Our preliminary studies suggest that these high levels do not contribute directly to the immunosuppressive effects of ascitic fluid.[31] It is not clear what immune functions IL-6 plays in such localized regions and whether high, sustained concentrations actively suppress or enhance other immune functions or whether they induce a state of nonresponsiveness through an indirect means.

The presence of high levels of IL-6 in several patients who have a low level of the surface antigen CA 125 suggests that the assay might contribute to the monitoring of such patients. However, because the correlation coefficient between the two markers is high, the lack of complementarity might diminish the utility of IL-6.

The relevance of tumor differentiation to IL-6 production cannot be drawn from this study, as there are too few with each tumor type, but it would be interesting to examine this to determine if such a correlation exists. The ovarian carcinoma marker CA 125 has been demonstrated to be associated with approximately 85% of serous ovarian tumors, 70% of undifferentiated tumors, and 30 to 40% of mucinous tumors.[2]

Evidence of Boltz et al.[20] regarding the lack of any significant amplification of the c-*ras*-Ki oncogene in ovarian tumors suggests that ovarian tumor progression may be related to abnormal growth factor regulation as opposed to inappropriate oncogene expression and amplification. However, evidence relating abnormal growth factor regulation to ovarian tumor progression has been demonstrated by the amplification and overexpression[19] of an epidermal growth factor–like receptor[21] encoded by the HER-2/*neu* oncogene. Also, recent reports have shown that macrophage colony–stimulating factor, the receptor for which is a product of the c-*fms* gene locus, also is secreted by many ovarian epithelial tumors.[32] While the unregulated expression of IL-6 has been implicated in the pathogenesis of numerous diseases, including some lymphoid malignancies,[33] it remains to be determined what role such deregulated expression of IL-6 has in the development and progression of ovarian cancer. However, the unregulated expression of this growth factor in the development of ovarian cancer may offer a means of abrogating tumor proliferation by regulating the factor or its genetic locus.

We would like to thank Dr. Tadamitsu Kishimoto and Dr. Toshio Hirano of Osaka University, Osaka, Japan, for providing rIL-6, and the IL-6–responsive cell line, MH60.BSF2; Dr. Robert C. Bast for advice and additional specimens; and Dr. Donna Vredevoe for the use of laboratory facilities.

Discussion

Dr. John Boyce, Brooklyn, New York. The search for efficient ovarian tumor–associated markers has been tedious and difficult. This study, using a cohort of 36 patients with 90 specimens, attempts to show that IL-6 correlates well with tumor burden, clinical disease status, and survival and consequently should be considered seriously as a useful tumor marker.

The role of a tumor associated–marker may be measured in two areas, the screening for the malignancy and the monitoring of the results of therapy. The information presented today shows a statistically significant difference in the IL-6 levels between the patients with ovarian carcinoma and the controls. There is an excellent correlation with gross disease and IL-6 in 21 patients. There is, however, a disturbing lack of a difference between 15 patients with microscopic disease

and 15 controls. No data were offered on the specificity or sensitivity of IL-6 measurements in the patients with ovarian cancer. Since the production of IL-6 is increased in bacterial infections and rheumatoid arthritis, an analysis of the specificity and sensitivity is essential to a conclusion of the efficacy of IL-6 as a marker for screening purposes.

The evaluations of IL-6 as a marker for monitoring the results of therapy is less complicated since the interindividual considerations are eliminated. Serial measurements were performed in 16 patients, and there was an excellent correlation with the clinical behavior of the patients. Thus IL-6 may be used very accurately for monitoring the progress of therapy. The poor correlation with microscopic disease will again limit severely the use of IL-6 in determining whether there is a complete response. It is interesting that the same limitation applies to CA 125, i.e., the greatest opportunity for use is in those patients with subclinical disease. IL-6 does not appear to have an advantage over CA 125, and there is also no complementary effect of IL-6 to CA 125.

The study design is simple and solid. The statistical analysis is adequate for the study. I wish to compliment the authors for the innovative work that they have accomplished in this study, taking the initiative in exploring new markers in ovarian carcinoma, a disease where 60% of the diagnoses are made in stages III and IV with 5-year survival of 20% and 10%. I have two questions for the authors: (1) How many of the 36 patients with ovarian cancer were untreated on entry to the study? (2) What were the epidemiologic characteristics of the control group?

Dr. Howard W. Jones III, Nashville, Tennessee. I would like to ask if this has the same problem as CA 125, that is, a positive test in other clinical situations, such as endometriosis or pelvic inflammatory disease, which would further limit its value as a screening test?

Dr. J. Donald Woodruff, Baltimore, Maryland. I think we certainly need steps like this because we're making very little progress in the early diagnosis of ovarian cancer.

When you state that this test was positive for ovarian cancer, are you referring to mucinous tumors and epithelial tumors of all types? Was there any difference in the positivity between the various histologic types?

Dr. Berek (Closing). I would like to thank Dr. Boyce for his thoughtful comments.

There were 19 patients in the group of 36 whose serum IL-6 levels were measured prior to the first chemotherapy. Most of the 16 patients who were monitored serially came from this group. Initially these patients were in a study where we measured serial CA 125 levels, so we reexamined those frozen sera. Of the patients measured serially, 15 had not received prior therapy before the first measurement. Many of the others had microscopic disease and were on intraperitoneal chemotherapy protocols when the serum IL-6 levels were measured. Therefore they had a laparotomy before the evaluation and a laparotomy at the end so that we could correlate the data.

The control group is a matched group of women without any evidence of disease. To determine the specificity and to address the question that Dr. Howard Jones raises about whether this is positive in other conditions, we would have to study a cohort of women with a variety of different benign conditions. We have not done this yet.

Regarding the sensitivity of this study, the value is 0.5 for the entire group, although this is 0.76 for those with macroscopic disease. This corresponds to sensitivities of 0.6 and 0.87, respectively, for core CA 125 measurements on the same sera.

Currently we are examining ways to improve the sensitivity and specificity of the assay. We are developing a refined IL-6 assay using a more specific enzyme-linked immunosorbent assay. Also, we plan to measure IL-6 levels in many fresh serum specimens and a larger control group.

To answer Dr. Woodruff's question, we did not find a particular correlation with pathologic results, perhaps because we have too few in the sample. There were several patients with mucinous tumors who did have positive IL-6. A known drawback of CA 125 is that many of those patients have negative assays.

However, it may well be that IL-6 is more important in the understanding of the fundamental tumor growth rather than as a useful tumor marker. Currently we are evaluating the elaboration and control of IL-6 expression by using antisense oliogonucleotides to modify gene expression of the growth factor. Also, we are using a murine model to study therapeutic approaches with monoclonal antibodies that are directed either toward the IL-6 gene product and other growth factors or their receptors. Since IL-6 is a constitutive product of the ovary and presumably related to angiogenesis, we hope that abrogation of expression of the genetic locus of the growth factor might delimit tumor proliferation or growth.

Ultrasonography in obstetrics and gynecology: The state of the art in 1990

Ultrasound panel

Introduction

Of the many technologic developments of the past quarter century, none has become as thoroughly integrated into the practice of obstetrics and gynecology as diagnostic ultrasonography. It is based on technology developed for military purposes in World War II, but its potential applicability to the solving of the mysteries of the uterus and its contents was first recognized by a canny Scot, Ian Donald, who played the role of St. Paul in disseminating and popularizing a new religion. Other "apostles" rose up and joined the movement, until today the pervasive influence of ultrasonography on obstetrics and gynecology has altered the discipline in fundamental and irrevocable ways. Practitioners under the age of 40 or 45 have difficulty imagining that pregnancy can be managed or that gynecologic disease can be dealt with unless high-frequency sound waves have been made to traverse a woman's body.

Ideally, development of technology should include the consideration of several important questions, with reasonably firm answers required before its incorporation into clinical use. As the first priority, is it safe? Then, what are its uses and limitations? Finally, what is the cost and is it cost-effective? In the case of ultrasonography, as indeed with other technologic developments in medicine, this sequence was not followed. Instead, the technique was introduced and adopted widely, no doubt influenced by the commercial interests of the makers and users of the equipment, before there was much in the way of logical consideration of these essential questions. Happily, in the case of ultrasonography, evidence accumulated over the past 20 years should be sufficient to convince all but the most skeptical of its safety. Much is now known about its use and limitations, and a consensus seems to be developing as to the circumstances where it is and is not helpful, although the issue of using routine ultrasonography for all pregnant women remains a thorny one. Many individuals have argued for its incorporation into routine antepartum care, although the official position (i.e., the 1984 National Institutes of Health Consensus Development Conference) calls for usage only "on indication." Much of this controversy hinges on the last question, cost effectiveness, which has not really been addressed in any serious way.

The American Gynecological and Obstetrical Society decided last year to ask a panel of its Fellows to address a specific clinical issue facing the specialty with a "position paper" to place that issue into current perspective and to identify future needs. Ultrasonography was an obvious choice for the first of these symposia. The members of the panel, Roy M. Pitkin, James A. Low, and J. Robert Willson, were selected presumably as interested observers, who together cover the breadth of the discipline but who lack any vested interest in ultrasonography.

The time allotted on the program meant that only a limited area of the field could be addressed. Through correspondence, telephone calls, and one meeting, the panel attempted to identify the most important aspects for consideration. A list of 12 or 15 potential topics was developed, discussed, and voted on. By this means, the panel arrived at three topics to present to you today, what we believe are the important issues regarding the use of ultrasonography in obstetrics and gynecology: (1) screening and detection of congenital malformation, (2) Doppler velocimetry, and (3) ultrasonography in gynecologic diagnosis.

Screening and detection of congenital malformation

Roy M. Pitkin, MD
Los Angeles, California

Congenital malformations often occur sporadically and unpredictably, and a method of population screening to identify at-risk pregnancies would be of great value. Routine ultrasonography has some appeal in this regard. Unfortunately, the literature indicates a relatively poor sensitivity, with usually 30% or less of malformations identified or suspected by this means. Substantially better results have been described with ultrasonography targeted on the basis of screening ultrasonography or clinical findings, but these studies involve highly selected subjects examined carefully by experienced ultrasonographers, and their results are not relevant to population screening. A questionnaire survey of experts in the field indicated disagreement with the separation of screening and targeted ultrasonography, widely varying estimates of the accuracy of either, and average charges of $209 and $263, respectively. Theoretical considerations of the various types of malformations, their frequencies, and the likelihood of ultrasonographic detection reveal a minority of defects in which ultrasonography is both accurate and useful clinically. Ultrasonography seems to be of little potential as a means of screening for congenital malformation because of relatively low sensitivity and uncertain cost effectiveness. (Am J Obstet Gynecol 1991;164:1045-8.)

Key words: Ultrasonography, congenital malformation

The prevalence of major congenital malformation (i.e., defects either incompatible with life or severe enough to interfere with normal living) is about 2% to 3%. For practical purposes the only "treatment" available is abortion; therefore methods of screening and detection generally must lead to a diagnosis before the midpoint of gestation. For this reason most screening programs involve testing at about 16 weeks' gestation.

Although abortion is the most obvious response to the diagnosis of a severely malformed fetus, it is not the only one. For women who choose to carry the pregnancy to term, knowledge of the fetal condition can influence obstetric and neonatal care, such as where and how delivery is to be accomplished. This type of information also can allow time for emotional adjustment and avoid the acute psychologic trauma accompanying the birth of an unexpectedly malformed infant. Finally, although the capacity to treat the fetus directly and thereby ameliorate or obviate the effects of a congenital abnormality is minimal at present, there is reason to believe this may become more applicable in the future.

A number of factors influence the usefulness of ultrasonography in the screening and detection of congenital malformation. Chief among these is the stage of gestation at which ultrasonography is performed. As outlined previously, the general rule is "the earlier the better," with respect to how the information will be used. However, the study's accuracy will generally increase as gestation advances, so from this perspective the rule is "the later the better." Determining factors of equal or even greater importance are the skill and experience of the ultrasonographer and the length of time spent in examination.

Literature review. Most of the arguments in favor of routine ultrasonography in pregnancy involve identifying gestational length accurately and recognizing multiple pregnancy. However, the potential also exists for the detection of congenital malformation. Thacker[1] reviewed the randomized clinical trials of routine ultrasonography reported before 1985; several more have been reported subsequently.[2,3] These studies have generally not found any improvement in pregnancy outcome, suggesting that either malformations have not been identified in sufficient quantities to influence outcome statistics or they have been identified but not aborted.

Several reports have addressed anomaly detection specifically. All involved retrospective analysis. Persoon and Kullander[4] described an experience with 43,000 scans in 22,400 patients; only 24% of anomalous fetuses were identified early enough to permit termination of pregnancy. Lys et al.[5] analyzed 8316 low-risk pregnan-

Ultrasound panel, presented at the Ninth Annual Meeting of the American Gynecological and Obstetrical Society, Hot Springs, Virginia, September 6-8, 1990.

Table I. Questionnaire survey of screening and targeted ultrasonography

	Screening	*Targeted*
Malformations suspected (%)		
Mean	66	87
SD	14	12
Range	37-90	50-99
Total charge ($)		
Mean	209	263
SD	67	94
Range	66-335	110-663

cies scanned routinely, with only 14% of malformations identified; the disappointing results were thought to reflect the fact that the examinations were not done by highly trained personnel and were not "targeted" to anomaly detection. In a small but carefully analyzed series of routine ultrasonographic scans done for no apparent clinical reason, Li et al.[6] calculated a sensitivity of 38% and a specificity of 99% for screening a low-risk population for fetal malformation. Similar results came from a study by Levi et al.[7]: sensitivity, 34.4% for all defects and 54.9% for major and detectable ones; specificity, 99.7% in both cases. Thus these reports are fairly consistent in indicating that ultrasonography for screening has a rather poor sensitivity but an excellent specificity. In other words, it is not good in detecting the malformed fetus but very good in ruling it out.

Compared with screening examinations, ultrasonography targeted specifically to possible fetal malformations has been reported to be substantially more accurate. Such studies typically are prompted by findings on screening ultrasonography, clinical characteristics, or history indicating high-risk status. Sabbagha et al.[8] reported on 615 women who underwent targeted imaging, usually but not always before 24 weeks' gestation; sensitivity was 96% and specificity 99%. Manchester et al.[9] described the experience of the University of Colorado program, in which 257 consecutive patients were referred at 12 to 40 weeks' gestation because fetal malformation was suspected on ultrasonography elsewhere. The program's evaluation included fetal echocardiography, if indicated, and involved a multidisciplinary team. Sensitivity was 99% and specificity 91% when each fetus was considered as a unit; however, 37% of the anomalous infants had malformations not suspected on ultrasonographic examination, in addition to defects which had been identified ultrasonographically. Hobbins et al.[10] and Hill et al.[11] reported experiences that, while not presented in sufficient detail to calculate statistics, seem generally similar. It must be emphasized that all these seemingly excellent results came from individuals with vast experience in ultrasonography who presumably devoted substantial amounts of time and attention in a thorough evaluation of each case. Moreover, the study populations must have been highly selective. Somewhat in contrast with this optimistic picture is a collection[12] of six anecdotal cases in which misinterpretations and errors in diagnoses led to unfortunate outcomes. Most often the mistake involved early delivery, which the authors pointed out is seldom necessary for the anomalous fetus.

Questionnaire survey. To sample current opinion of ultrasonographers about screening and detection of fetal malformation, a simple questionnaire was sent to 46 individuals regarded as experts in obstetric ultrasonography by virtue of articles they had written. Most, but not all, of those surveyed are in full-time academic practice. The questionnaire was divided into two parts, one dealing with screening, or level I, ultrasonography and the other with targeted, or level II, ultrasonography. Each respondent was asked to estimate what percentage of "clinically significant fetal malformations" would be suspected by screening ultrasonography and diagnosed by targeted ultrasonography, with gestational age unstated. He or she also was asked about the total charge for these procedures in his or her unit.

Questionnaires were returned by 11 of 20 radiologists and 25 of 26 obstetrician-gynecologists, for an overall return rate of 78%. None of the differences between the two medical specialties was statistically significant, and the results are presented together. A number of respondents regarded the distinction between screening, or level I, and targeted, or level II, ultrasonography as artificial and inappropriate, presumably reflecting the attitude of national organizations.[13] One even characterized it as a "refuge of the inexperienced and incompetent sonographer." Others simply stated that they did not do a less than complete examination in their units. Only five of 11 radiologists and 13 of 25 obstetricians gave different responses for screening and targeted ultrasonography. Therefore the data for screening sonography should be regarded cautiously.

From the results of the survey (Table I) it is clear that estimates vary widely with respect to the proportion of fetal malformations that may be suspected or diagnosed ultrasonographically. The average estimate is about two thirds by a screening approach and about seven eighths by the more detailed targeted technique. The reported charges varied even more widely, as much as sixfold ($110 to $663) for the advanced study.

Hypothetical considerations. The final segment of this portion of the symposium involves a theoretical approach to what might be possible by antenatal diagnosis of fetal malformation. To make such an analysis, it is necessary to know the relative frequency of various birth defects. The report by Heinonen et al.,[14] which is based on the Collaborative Perinatal Project and published in 1977, represents one source of such information. Among the 50,282 pregnant women en-

rolled, the prevalence of malformed infants was 6.5% and of total malformations 8.8%. Slightly more than half of the malformations were considered major, defined as potentially life-threatening or representing major cosmetic defects. Table II lists the occurrence rates of various defects grouped by organ system.

Musculoskeletal system. The most common defects, in order, were clubfoot, polydactyly-syndactyly, absent or hypoplastic muscle or limb, and dislocated hip. Ultrasonographic diagnosis is questionable and moreover the defects are generally amenable to surgical treatment and correction. Thus ultrasonography has little to offer.

Genitourinary system. Hypospadias, by far the most common defect in this group, is not diagnosable by ultrasonography and is eminently treatable after birth. Polycystic kidneys may be diagnosed ultrasonographically, but whether such a diagnosis before 20 weeks' gestation would justify abortion is arguable. Obstructive uropathy can certainly be diagnosed by ultrasonography and theoretically may benefit from treatment in utero, although the experience with urinary shunting has not been encouraging. Thus ultrasonography is a limited value in genitourinary malformations.

Cardiovascular system. The most common malformations (septal defects, valvular stenosis, patent ductus arteriosus) are usually amenable to surgical treatment after birth. Some less common ones (e.g., hypoplastic left heart, malposition of vessels) are more serious, and early identification with subsequent abortion has some appeal. However, conventional ultrasonography is of limited value in identifying the fetus with congenital heart defects. Without unusual findings such as hydrops or cardiac arrythmia, it is not likely to be helpful. Approaches that include fetal echocardiography offer considerably more potential for diagnosis. However, fetal echocardiography requires special expertise of a type currently found in very few centers.

Gastrointestinal system. The two most common conditions, pyloric stenosis and anal atresia, are not diagnosed by ultrasonography and are easily treated after birth. Less common defects such as omphalocele and gastroschisis, tracheoesophageal fistula, and small bowel atresia can be diagnosed ultrasonographically; such an antenatal diagnosis is likely to be helpful in planning delivery and neonatal care. Additionally, recognition of omphalocele should prompt karyotyping because of the high association of omphalocele and aneuploidy.

Central nervous system. Microcephaly and hydrocephalus are the two most common defects. The former is not generally amenable to ultrasonographic diagnosis, at least early enough for elective abortion. Hydrocephalus is diagnosable by ultrasonography and is, potentially at least, amenable to treatment in utero; however, the experience with shunting procedures has been mixed.

Table II. Prevalence of malformations

System	*Rate (per 1000)*
Musculoskeletal	14.3
Genitourinary	9.2
Cardiovascular	8.0
Gastrointestinal	6.0
Central nervous	5.3
Respiratory	4.3
Syndromes	3.5
Eye and ear	2.4

Data of Heinonen et al.[14]

Table III. Ultrasonographic signs in Down syndrome

	Sensitivity (%)	*Specificity (%)*
Femur length shortening		
Perella et al.[17]	42	88
Dicke et al.[18]	15	90
Cuckle et al.[19]	11	98.6
Grist et al.[20]	50	93.5
Hill et al.[21]	50	85
Biparietal diameter/femur length		
Dicke et al.[18]	18	85
Hill et al.[21]	36.4	93.4
Lockwood et al.[23]	51-70	93-95
Shah et al.[23]	18	94

Respiratory system. The most common defect, cleft lip or palate, conceivably can be recognized ultrasonographically but probably should not lead to abortion. Diagnosis of lung hypoplasia by measuring thoracic diameters has been disappointing; besides, the condition in its severe form is universally fatal. Diaphragmatic hernia can be diagnosed and it has been suggested recently that fetal surgery may offer some benefit.

Syndromes. The most common of these conditions is Down syndrome, and it represents something of a paradigm. Ultrasonographic signs (decreased femur length and increased nuchal skinfold thickness) were reported initially to have a sensitivity of 75% and a specificity of 98%.[15] However, an editorial[16] accompanying this initial report urged physicians "to resist the temptation to introduce ultrasound screening for Down's syndrome into widespread practice before these findings are confirmed by others." How prescient, for subsequent reports (Table III) have yielded widely varying results, especially with respect to sensitivity. Some means of screening for Down syndrome and other aneuploides is much needed and is the focus of considerable effort. However, it seems unlikely that ultrasonography can ever be cost-effective for this purpose. Moreover, it is hard to imagine that it will ever replace karyotyping as the means of diagnosis.

Eye and ear. Cataract, the most common defect in this class, is neither amenable to ultrasonographic diagnosis nor an indication for abortion. Anophthalmia and microphthalmia can be detected by careful ultrasonographic examination, but diagnosis would not likely alter management.

Comment

Although there has been much interest in ultrasonography in the screening and detection of congenital malformation, careful and objective review makes it difficult to generate much enthusiasm for the subject. As a screening test, it fails because of a generally abysmal sensitivity, although specificity is good. Screening tests must stand or fall primarily on the basis of their ability to detect the disease when it is present.

When used for detection of malformations suspected because of history or screening ultrasonography, the targeted examination looks better. Careful study by a skilled ultrasonographer can identify many—though by no means all—malformations. However, this is a higher, labor-intensive process and therefore extremely expensive. If, as Sabbagha et al.[8] stated, an average of one hour is spent in the assessment, our survey's estimate of $250 to $300 may be lower than it should be. Clearly, an appropriate cost-benefit analysis needs to be done regarding this question.

The current status of maternal and fetal blood flow velocimetry

J.A. Low, MD
Kingston, Ontario, Canada

Significant progress has been achieved in regard to normative data for uteroplacental and fetal blood flow velocity and the factors which may affect these observations. Associations have been demonstrated between abnormal indices of maternal and fetal blood flow velocity and pregnancy-induced hypertension, fetal growth retardation, fetal blood gas measures, and intrapartum clinical fetal distress. However, in general, the predictive power is modest and no evidence has yet been provided to indicate that these measures can be used as a screening test in the general obstetric population. Continuing research is highly desirable. At the present time, the use of Doppler assessment of blood flow in pregnancy should be limited to the investigational setting. (Am J Obstet Gynecol 1991;164:1049-63.)

Key words: Blood flow velocimetry, hypertensive disorders, growth retardation, fetal asphyxia

It is well recognized that compromised uteroplacental or fetal circulation may play an important role in hypertensive disorders in pregnancy, intrauterine growth retardation, and fetal asphyxia. In the past, the clinical assessment of maternal and fetal hemodynamics has not been possible. However, the development of Doppler ultrasonographic technology, particularly during the last 10 years, has provided an opportunity to obtain both qualitative and quantitative assessment of maternal and fetal hemodynamics in a noninvasive manner.

A National Institutes of Health consensus conference in September 1986 reviewed the development of Doppler ultrasonography. It was emphasized that even if altered velocity was confirmed as being able to detect fetal compromise with sensitivity and specificity, additional clinical trials would be necessary to determine whether intervention that is based on Doppler findings actually improved outcome. One conclusion of the conference stated, "It is desirable to limit the use of Doppler assessment in pregnancy to the investigational setting until the appropriate clinical trials are concluded."

The objective of this review is to examine the current understanding of measures of maternal and fetal blood flow velocity and the role of these measures in the assessment of particular maternal and fetal complication.

Measurement of maternal and fetal blood flow

Accurate measures of blood flow would be ideal. Estimates of uteroplacental blood flow have been obtained from the uterine artery with a transvaginal probe.[1] This study reported an approximate fourfold increase of blood flow in the uterine artery at term in relation to prepregnancy values.

The results of fetal blood flow studies in the umbilical vein and aorta are outlined in Table I. Measures of fetal blood flow per kilogram of body weight per minute during the last trimester have been reasonably comparable. The proportion of umbilical vein to aortic blood flow has ranged from 50% to 64%. The ratio of umbilical to aortic flow remains constant between 26 weeks and term.[12]

However, there are several sources of error in the measurement of maternal and fetal blood flow. The calculation of mean blood flow requires an accurate measure of blood flow velocity. The formula for the calculation of mean blood flow velocity from the waveform may vary, and errors of the order of 20% may occur in the estimation of the angle of insonation.[6] Small errors in the measurement of vessel diameter are compounded in the calculation of blood flow.

Estimates of error of <10% to 15% have been reported with special instrumentation and careful attention to the sources of error.[13] Thus there is a role for measures of blood flow in clinical research in dedicated centers. However, errors up to 50% are perfectly realistic when commercially available sector scanners with minimal signal processing are used.[14] In addition, wide SDs of the available reference data limit the predictive value of measures of blood flow.[15] Thus, because of these methodologic problems, blood flow measurements have been largely abandoned in clinical studies.

Measurement and maternal and fetal blood flow velocity

Maternal and fetal blood flow velocity indices avoid the major sources of error in the measurement of blood

Ultrasound panel, presented at the Ninth Annual Meeting of the American Gynecological and Obstetrical Society, Hot Springs, Virginia, September 6-8, 1990.

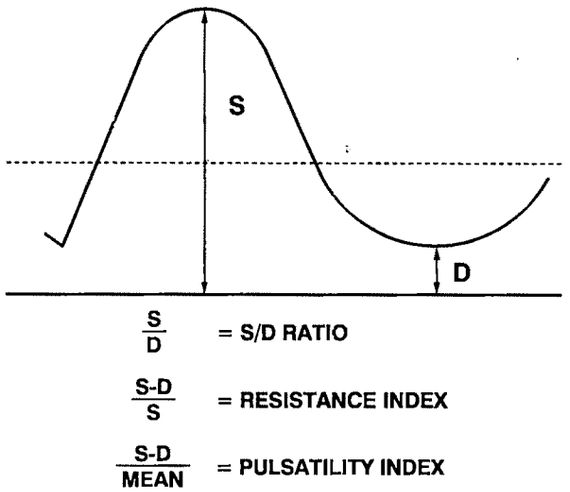

Fig. 1. Indices of maternal and fetal blood flow velocity.

flow. These indices are independent of the angle of insonation and do not require a measurement of the diameter of the vessel. There is a close correlation in normal pregnancies between the three indices used in most clinical studies[16] (Fig. 1). The systolic/diastolic ratio[17] and the Pourcelot resistance index[18] are the simplest indices to measure. However, errors increase with absent end-diastolic velocity so that systolic/diastolic ratios approach infinity or the resistance index approaches one. The pulsatility index[19] requires digitizing the entire waveform, making it the least convenient index. Variations of the pulsatility index reported by different centers may reflect differing methods of calculating mean blood flow velocity in commercially available analyzers.[20, 21] Although the pulsatility index incorporates additional information in regard to the waveform, the extra computation does not contribute significantly to current clinical interpretation.[22, 23]

Signals of the distinctive maternal and fetal waveforms can be obtained by either pulsed wave or continuous wave Doppler equipment. No significant difference has been reported for waveform measures obtained by these two techniques.[24] However, a better correlation between continuous wave and pulsed wave measures has been observed in the umbilical artery rather than in the uterine artery.[25]

Interobserver and intraobserver variation has been specifically examined by several investigators.[26-29] No significant differences have been reported with, in general, a coefficient of variation <10%.

A waveform analysis yields information relating to the condition of the proximal circulation and the impedance of the distal vascular bed. These relationships have been examined in the laboratory. A computerized model simulating uteroplacental waveforms has demonstrated that increasing uteroplacental vascular resistance caused an increase of the systolic/diastolic ratio or the pulsatility index with the appearance of a dicrotic notch. Alterations of blood pressure in this model influenced mean blood flow velocity but had little effect on these indices.[30] In the laboratory, embolization of the fetal side of the placental circulation in the fetal lamb results in a decrease of end-diastolic velocity to zero, with a resultant increase of the umbilical artery systolic/diastolic ratio.[31, 32] A similar change has been demonstrated in the exteriorized fetal lamb by constriction of the umbilical vein, resulting in retrograde end-diastolic flow in the umbilical artery and aorta.[33]

Thus in clinical studies waveforms with a high flow in diastole accompany a low downstream impedance, whereas waveforms with little flow, or reversed flow during diastole, are seen when impedance downstream is high. There is an increasing body of evidence to indicate that elevated indices of blood flow velocity in the fetal circulation reflect a specific microvascular pathologic condition in the tertiary villi of the placenta. Examination of the placenta from patients with elevated systolic/diastolic ratios demonstrates a striking reduction of the number of small muscular arteries in the tertiary villi.[34-36]

Reference values for maternal and fetal blood flow velocity. The uteroplacental circulation, including the uterine, arcuate, radial, and spiral arteries, is complex. This circulation undergoes remarkable changes during pregnancy to accommodate the growing fetus. The trophoblast invades the spiral arterioles, replacing the musculoelastic component of the vessel wall and reducing peripheral resistance to permit this accommodation.

The main stem uterine arteries may be identified with a duplex sector scanner and a vaginal probe.[37] The uterine arteries also may be examined abdominally, with identification of the distinctive uterine artery waveform.[38] Alternatively, the arcuate arteries may be examined in a placental or nonplacental site. However, abdominal observations of the radial or arcuate arteries represent one vessel in a complex circulation, so that reproducible identification of an arcuate artery is difficult.

Reference values of uteroplacental blood flow velocity from uncomplicated pregnancies reported by a number of investigators are outlined in Table II. Indices of uteroplacental blood flow velocity decrease in early pregnancy until 20 to 26 weeks' gestation and then remain stable to term. The high end-diastolic blood flow velocity and low ratios during the last half of pregnancy reflect the low peripheral vascular resistance of the placenta.

The sampling site must be known. Indices of blood flow velocity tend to be lower in the arcuate artery than

in the uterine artery. Indices are lower in placental than in nonplacental sites.[41, 42] These differences are particularly striking in the second trimester, when differences up to 50% may occur between observations from nonplacental and placental sites in the arcuate and uterine arteries.[42]

Reference values of fetal aortic blood flow velocity from uncomplicated pregnancies as reported by a number of investigators are outlined in Table III. The indices of vascular resistance in the fetal aorta remain unchanged during the last half of pregnancy. The relatively high indices reflect the low end-diastolic blood flow velocity due to the vascular resistance of the nonplacental circulation. Since the mean blood flow velocity in the fetal aorta is constant, the increase in total blood flow is due to the increase in the diameter of the fetal aorta from 3 or 4 mm to 7 or 8 mm during the last half of pregnancy.[12, 47]

Umbilical artery blood flow velocity indices are lower at the placental than the fetal end of the cord.[48-50] Thus the usual protocol is to record blood flow velocity observations from the placental end of the cord. Reference values for umbilical artery blood flow velocity for uncomplicated pregnancies reported by a number of investigators are outlined in Table III. Indices prior to 20 weeks' gestation are of limited value because of either low or absent end-diastolic velocity. Although there is some variation in the reported mean values for each gestational age, there was a decrease of all indices during the last half of pregnancy. A similar pattern has been observed in studies of twin pregnancies.[38, 60] The wide 95% confidence limits, particularly in the second trimester, represent a limitation in the identification of compromised pregnancies at this stage.[51]

Reference values for the fetal cerebral circulation blood flow velocity from uncomplicated pregnancies reported by a number of investigators are outlined in Table III. Observations have been made in the common carotid artery,[45] the internal carotid artery,[41, 62] and the middle cerebral artery.[46, 61] Common carotid end-diastolic velocity was not observed until 32 weeks' gestation because of the vascular impedance of the external carotid vascular bed. Middle cerebral artery end-diastolic blood flow velocity is absent or low with corresponding high indices until 28 to 32 weeks' gestation. Thereafter there is a significant decrease of all indices to term,[46, 61, 62] reflecting decreased vascular re-

sistance in the cerebral circulation. It has been speculated that these changes are a response to changing fetal blood gases with advancing gestational age.[45]

Factors affecting maternal and fetal blood flow velocity. There is an inverse relationship between fetal heart rate and blood flow velocity in the umbilical artery, fetal aorta, and carotid artery. A significant negative correlation has been observed between fetal heart rate and umbilical artery systolic/diastolic ratios or pulsatility index in the antepartum period[63-65] and in the intrapartum period.[63, 66] A similar correlation has been observed in the fetal aorta and carotid artery.[64] Although the response may be variable, spontaneous or induced fetal heart rate accelerations have been associated with decreased umbilical artery systolic/diastolic ratios.[66, 67] However, no significant correlation was observed for the normal range of fetal heart rates between 120 and 160 beats/min and umbilical artery systolic/diastolic ratios.[68] Thus, although there is an association between fetal heart rate and blood flow velocity, at this time it is not considered sufficient to influence clinical interpretation of fetal blood flow velocity waveforms.

Several factors affecting maternal and fetal heart rate have been examined. Smoking a single cigarette is associated with an increase of maternal heart rate and blood pressure; however, no change in uteroplacental blood flow velocity was observed.[69] Maternal smoking is also associated with an increase in fetal heart rate.[70-72] This fetal tachycardia was associated with an increase in blood flow velocity and a transient decrease of the pulsatility index in the fetal aorta and umbilical artery.[70, 71] Graded maternal exercise is associated with an increase in maternal heart rate and blood pressure and fetal heart rate. However, no consistent changes in uteroplacental or umbilical artery systolic/diastolic ratios have been observed with exercise.[72, 73]

Blood viscosity may affect blood flow velocity. However, in current clinical studies no association has been observed between maternal blood viscosity and uteroplacental blood flow velocity or between fetal blood viscosity and umbilical artery blood flow velocity.[74-76]

Laboratory studies have demonstrated that behavioral state will affect regional blood flow, particularly to the brain.[77, 78] Studies at term[79] and at 27 to 28 weeks' gestation[80] have demonstrated a reduction in the pulsatility index in the fetal internal carotid artery and the fetal aorta during the active sleep state in relation to the quiet sleep state.

of preterm labor on blood velocity have been examined. Oral nifedipine had no apparent effect on uteroplacental or fetal blood flow velocity.[81] Similarly, magnesium sulfate was associated with no change in maternal or fetal blood flow velocity.[82] However, ritodrine, with an increase in maternal and fetal heart rate, was associated with a progressive decrease in both uteroplacental and umbilical artery systolic/diastolic ratios.[82] Maternal use of indomethacin was not associated with a significant change in umbilical artery systolic/diastolic ratio.[83] However, in the presence of ductal constriction and tricuspid insufficiency, indomethacin may be associated with a decrease in the pulsatility index in the middle cerebral artery.[84]

Spontaneous uterine contractions of labor result in a progressive decrease of uteroplacental end-diastolic blood flow velocity. The intensity of the contraction correlates with the decrease of the end-diastolic velocity.[85] In one study[86] the end-diastolic velocity reached zero with intrauterine pressures >35 mm Hg. Umbilical artery systolic/diastolic ratios are unchanged during labor in the absence of fetal heart rate decelerations. Epidural analgesia during labor or anesthesia at delivery has no apparent effect on uteroplacental or umbilical artery blood flow velocity.[87, 88]

Prediction of hypertension in pregnancy

It has been proposed that abnormal uteroplacental waveforms may identify obstetric patients at risk for hypertension in pregnancy.[89] Evidence to demonstrate this association is outlined in Table IV. Two studies examined hypertension in pregnancy from various causes. Trudinger et al.[39] observed abnormal uteroplacental waveforms in 11 of 25 patients with hypertension. Ducey et al.[91] reported the results for 136 patients with hypertension. The percentages of patients with a uteroplacental systolic/diastolic ratio >2.6 after 26 weeks were as follows: chronic hypertension, 12%; pregnancy-induced hypertension, 26%; and toxemia of pregnancy, 56%.

Two studies examined the predictive value of uteroplacental blood flow velocity at 18 to 20 weeks' gestation. Campbell et al.[89] examined 126 consecutive obstetric patients, 15 of whom had pregnancy-induced hypertension. Ten patients (64%) had a uteroplacental resistance index >0.58. The authors concluded that an abnormal arcuate artery blood flow velocity observation could be a valuable predictor of pregnancy-induced hypertension. Arduini et al.[90] reviewed 60 pregnancies at risk, 22 of which subsequently developed pregnancy-induced hypertension. The obstetric patients with hypertension had a higher uteroplacental resistance index than those with a normal blood pressure. The predictive characteristics of an abnormal uteroplacental resistance index were: sensitivity, 64%; specificity, 84%; positive predictive value, 70%; and negative predictive value, 80%.

One study did not demonstrate an association between uteroplacental blood flow velocity and pregnancy-induced hypertension. Hanretty et al.[92] in a matched cohort study compared 32 patients with untreated pregnancy-induced hypertension with 32 patients with normal blood pressure. Serial Doppler observations were obtained, and the lowest resistance index was used for analysis. There was no significant difference between the uteroplacental pulsatility index of the hypertensive group and the control group. High and low pulsatility indices were found in both groups, with occasional divergent indices occurring in the same patient.

Prediction of fetal growth retardation

Three studies have examined the relationship between the final uteroplacental blood flow velocity observation before delivery and fetal growth retardation at delivery. Trudinger et al.[39] reported low end-diastolic blood flow velocity in 15 of 25 growth-retarded newborn infants and suggested that a change in uterine perfusion was a primary event in some cases of growth retardation. McCowan et al.[93] reported reduced end-diastolic blood flow velocity in seven of 12 growth-retarded newborn infants. Six of these seven cases occurred in pregnancies complicated by severe toxemia. However, Gudmunsson et al.,[56] in a study of 129 selected pregnancies of whom 66 delivered growth-retarded infants, observed no significant difference in the mean resistance index for growth-retarded infants in relation to normal infants.

Three studies reported data assessing the predictive value of uteroplacental blood flow velocity in growth

Table V. Predictive value of uteroplacental blood flow velocity for growth retardation in newborns

SGA, Small for gestational age.

retardation (Table V). The design was different in each study. Trudinger et al.,[39] using the final uteroplacental blood flow velocity observation before delivery, reported a sensitivity of 60% with a positive predictive value of 53%. Chambers et al.[94] examined the predictive value of a single uteroplacental blood flow observation during the last trimester in 145 selected patients, 85 of whom were delivered of growth-retarded infants. There was no significant difference in the mean resistance index for the growth-retarded infants in relation to the normal infants. The resultant sensitivity of this single observation was low, 29%, with a positive predictive value of 66%. Jacobson et al.[95] examined the predictive value of uteroplacental blood flow velocity measures at 20 and 24 weeks' gestation to growth retardation at delivery in 93 selected pregnancies. There was evidence of an association between a higher mean resistance index at both 20 and 24 weeks and growth retardation at delivery. A reasonable sensitivity, 70%, was achieved; however, the positive predictive value was 33%. The authors concluded that the high false-positive rate would limit the clinical value of such observations.

A number of descriptive studies of fetal blood flow velocity in the aorta[96, 97] or the umbilical artery[59, 94, 98-102] in growth-retarded infants have demonstrated an association between abnormal indices of blood flow velocity and growth retardation. The incidence of abnormal fetal blood flow velocity in the growth-retarded infants in these studies ranged from 60% to 83%.

There have been differences in the design of a number of studies which have examined the predictive value of umbilical artery blood flow velocity for fetal growth retardation (Table VI). Most study populations have been of selected-risk pregnancies with two studies of unselected pregnancies. The umbilical artery blood flow velocity observations have been either the last observation before delivery, serial observations during the third trimester, or observations at specific gestational ages.

Giles et al.[103] examined the relationship between the final umbilical artery blood flow velocity observation before delivery and growth retardation. All 10 growth-retarded infants had an abnormal umbilical artery systolic/diastolic ratio.

The relationship between serial umbilical artery blood flow velocity observations in the third trimester and fetal growth retardation has been examined in four studies. Fleischer et al.[104] observed a significantly higher umbilical artery systolic/diastolic ratio in newborn infants in the first quartile in relation to those with a weight/gestational age percentile greater than the first quartile. The sensitivity of an abnormal umbilical artery systolic ratio for growth retardation was 75%. Three studies in selected pregnancies reported a less favorable association, with a sensitivity of <50%. Divon et al.[105] found that ultrasonographic estimation of fetal weight (sensitivity, 87%) was a better predictor than the umbilical artery systolic/diastolic ratio. Berkowitz et al.[106] observed that the predictive value of the final umbilical artery blood flow velocity observation was superior to observations earlier in the third trimester. Dempster et al.[107] noted the large number of false-positive results, in addition to the limited sensitivity of umbilical artery blood flow velocity during the third trimester.

Two studies[108, 109] have examined umbilical artery blood flow velocity at specific gestational ages in selected pregnancies. There was a significant association between increased umbilical artery systolic/diastolic ratios or pulsatility index and growth retardation. The sensitivities were 53% and 65%, and the positive predictive values were 66% and 50%.

Two studies have examined umbilical artery blood flow velocity in large unselected populations. Sijmons et al.[110] reported a study of 400 unselected pregnancies in a tertiary care center with an overall 20% incidence of growth retardation. Umbilical artery blood flow velocity observations were performed at 28 and 34 weeks. The prediction for growth retardation was poor at both gestational ages. It was not improved by combining the two observations. Beattie and Dornan[111] reported a study of 2097 unselected singleton pregnancies. Um-

bilical artery blood flow velocity observations were obtained at 28, 34, and 38 weeks. The prediction of growth retardation was poor at each gestational age. The prediction, on the basis of a low ponderal index in both studies, was of the same order as the prediction of infants less than the 10th centile for weight/gestational age.

Preliminary experience has demonstrated that recording fetal carotid artery blood flow velocity may be difficult. Wladimiroff et al.[112] obtained satisfactory waveforms in 74% of pregnancies studied. Technical difficulties included maternal obesity, fetal head in the occipitoanterior position, and fetal movement. Two studies have reported a significantly lower carotid artery pulsatility index in the growth-retarded fetus than in the normally grown one.[108, 112] This decreased vascular resistance is postulated to reflect the redistribution of blood flow to the brain in the stressed fetus. However, Satoh et al.[101] observed a decrease in the carotid artery pulsatility index only in the growth-retarded fetus with fetal heart rate decelerations. One study[102] did not find a significant difference in the carotid artery pulsatility index in the growth-retarded fetus as compared with the normally grown fetus.

Association between fetal blood flow velocity and fetal blood gas values

The introduction of cordocentesis provided an opportunity to examine the relationship between fetal blood flow velocity and fetal blood gas and acid-base characteristics. Three studies have examined these relationships (Table VII). Two studies[113, 114] have demonstrated a significant correlation between increasing mean blood flow velocity in the fetal aorta and favorable umbilical vein oxygen tension, carbon dioxide tension, and pH. Similarly, a correlation has been demonstrated between decreasing pulsatility index in the umbilical artery[115] and aorta[114] and favorable umbilical vein blood gases.

Simonazzi et al.[116] examined the relationship between the internal carotid artery pulsatility index and blood gases and acid-base measures from the fetal scalp in 17 normal term pregnancies. There was a positive correlation between the pulsatility index in the internal carotid artery and fetal oxygen tension, suggesting that fetal oxygen tension has a regulatory role in cerebrovascular resistance under physiologic conditions.

Nicolaides et al.,[117] in a study of 59 growth-retarded fetuses with absent umbilical artery end-diastolic blood flow velocity, sampled the umbilical vein by cordocentesis. Hypoxia (oxygen tension <2 SD below the mean) was observed in 80%, and acidosis (pH <2 SD below the mean) was observed in 46%.

Some evidence of a relationship between fetal blood flow velocity and umbilical vein and artery blood gases at delivery has been reported. Ferrazzi et al.[115] in a study of 12 fetuses at delivery demonstrated a good correlation between umbilical artery blood flow velocity and umbilical vein and artery oxygen tension, carbon dioxide tension, pH, and lactate. Two studies have demonstrated a relationship between absent umbilical artery end-diastolic velocity and fetal blood gases at delivery. Brar et al.[118] observed an increased incidence of acidosis (umbilical artery pH <7.2). Tyrrell et al.[119] observed an increased incidence of hypoxemia and acidosis (umbilical vein <7.25).

However, the relationship of fetal blood flow velocity to fetal blood gases at delivery has not been consistent, with four studies failing to demonstrate a significant association. Laurin et al.[120] did not find a relationship

between aortic blood flow velocity and cord blood acidosis at delivery. McCowan et al.[121] in 15 severely growth-retarded fetuses reported no association between umbilical artery pulsatility index and cord blood gases at delivery. Divon et al.[122] reported similar umbilical artery pH in a matched cohort study of fetuses with normal and abnormal umbilical artery systolic/diastolic ratios. Lowery et al.[123] observed the same incidence of low pH in fetuses with normal and abnormal umbilical artery systolic/diastolic ratios.

Prediction of clinical fetal distress

A wide range of studies has addressed the question of predicting clinical fetal distress. Study populations have included pregnancies producing growth-retarded fetuses, postterm pregnancies, pregnancies at risk because of one or more maternal, obstetric, or fetal complication, or general obstetric populations. Maternal or fetal blood flow velocity observations have been obtained at varied times between 18 weeks and early labor. The outcome measures have usually been clinical fetal distress leading to intervention by either operative vaginal delivery or cesarean section. Diagnosis of fetal distress has been based on some combination of meconium in the amniotic fluid or abnormality of fetal heart rate, including decreased baseline variability or fetal heart rate decelerations.

Two studies of selected-risk pregnancies have provided data on the association of uteroplacental blood flow velocity and fetal distress in labor. Schulman et al.[124] in a study of 71 selected pregnancies observed a higher incidence of fetal distress in pregnancies with abnormal uteroplacental systolic/diastolic ratios (27%), in relation to pregnancies with normal systolic/diastolic ratios (5%). On the other hand, Brar et al.[125] in a study of 92 selected pregnancies observed no association between uteroplacental systolic/diastolic ratios and fetal distress.

Four studies of selected-risk pregnancies have provided data on the association between fetal blood flow velocity and fetal distress in labor. Three studies have demonstrated a significant association between absent end-diastolic velocity in the aorta[120, 126] and umbilical artery[127] and fetal distress in labor. Brar et al.[128] presented data to indicate that measurement of umbilical artery blood flow velocity can identify the late decelerations observed before or in early labor that are predictive of fetal distress.

Two studies of growth retardation have examined the association between umbilical artery blood flow velocity and fetal distress in labor. Rochelson et al.[129] in a study of 54 pregnancies producing growth-retarded infants observed fetal distress in 20 of 38 (53%) with abnormal umbilical artery systolic/diastolic ratios. Brar et al.[118] in a study of eight pregnancies with growth retardation in which reversed end-diastolic velocity reflected the severe end of the placental vascular resistance spectrum observed fetal distress during labor in six of the eight cases (75%).

Four studies of postterm pregnancies have examined the association between uteroplacental and fetal umbilical artery blood flow velocity and fetal distress in labor. Rightmire et al.[130] observed a small increase in umbilical artery pulsatility index in the postterm fetus with fetal distress. However, three studies have found no evidence that uteroplacental[131] or umbilical artery blood flow velocity[131-133] can identify the postterm fetus at risk of fetal distress during labor. The nonstress test proved to be a better predictor of fetal distress in these pregnancies.[131, 133] These authors concluded that maternal or fetal blood flow velocity studies are unlikely to be useful in the assessment of fetal status in prolonged pregnancy.

Five studies of selected-risk pregnancies have provided data on the predictive value of fetal blood flow velocity for fetal distress during labor (Table VIII). Two studies have demonstrated that absent end diastolic blood flow velocity in the fetal aorta[134] and in the umbilical artery[135] may be useful predictors of fetal distress with a sensitivity of 83% and 75%, respectively. However, abnormal umbilical artery blood flow velocities, as defined in these studies, are not as effective as predictors, with sensitivities ranging from 33% to 57%. The limitations of these observations are further emphasized by the low positive predictive values, ranging from 24% to 50%. Several authors note that the ab-

normal blood flow velocity observations precede other measures of fetal state and as such may prove to be useful complementary observations to the nonstress test and biophysical profile in the prediction of fetal distress.

Two random studies of obstetric populations have provided data on the predictive value of maternal and fetal blood flow velocity for fetal distress during labor. Hanretty et al.[133] examined 357 random pregnancies between 26 and 30 weeks' gestation. Newnham et al.[139] examined 535 random pregnancies at 18, 24, 28, and 34 weeks. Both studies concluded that uteroplacental blood flow velocity measures at these particular gestational ages were of little value in the prediction of clinical fetal distress in labor. Similarly, although there was some evidence of an association between abnormal umbilical artery blood flow velocity at these particular gestational ages and clinical fetal distress during labor, both the sensitivity and positive predictive values are low.

Two random studies of obstetric patients have examined the relationship between umbilical artery blood flow velocity in early labor and clinical fetal distress in labor. Feinkind et al.[140] observed an association between abnormal umbilical artery systolic/diastolic ratios and fetal distress. However, both the sensitivity and positive predictive values were low (Table VIII). Sarno et al.,[141] in a smaller study, found no relationship between abnormal umbilical artery systolic/diastolic ratios in early labor and clinical fetal distress during labor.

Prediction of low Apgar scores at 5 minutes

A number of studies have examined the relationship between fetal blood flow velocity and Apgar scores <7 at 5 minutes. No correlation was reported in four studies.[121, 134, 138, 140]

Data regarding the incidence of Apgar scores <7 at 5 minutes in relation to normal and abnormal fetal blood flow velocity are outlined in Table IX. No significant relationship between abnormal fetal blood flow velocity and low Apgar score at 5 minutes was identified. The only exception was reported by Brar et al.[128] The predictive value of an umbilical artery systolic/diastolic ratio >3.5 in the last trimester was a sensitivity of 53% and a positive predictive value of 38%.

Comment

Many investigators have contributed to the current understanding of normative data for both maternal and fetal blood flow and blood flow velocity and the factors that may affect these observations. However, in spite of this progress, the role of Doppler velocimetry in clinical practice has yet to be determined.

Measurements of maternal and fetal blood flow would be ideal. However, the well-documented sources of error in the measurement of blood flow limits the use of these measures to carefully designed research projects. Thus current clinical studies are examining measures of maternal and fetal blood flow velocity. A statement of procedure is important in the absence of a standardized protocol. The uteroplacental blood flow velocity will differ, particularly in the second trimester, if sampled in the uterine or arcuate arteries at a placental or nonplacental site. Measures in the fetal circulation are most easily achieved in the umbilical artery, preferably from the placental end of the cord. Observations in the fetal aorta and cerebral circulation will not be satisfactory for technical reasons, in some cases, and interpretation of the results may be more difficult because of the rather low end-diastolic velocity in these vessels.

Reference data derived from uncomplicated pregnancies have been obtained for uteroplacental blood flow velocity and fetal blood flow velocity in the umbilical artery, aorta, and cerebral circulation. The absence of end-diastolic blood flow velocity limits the interpretation of uteroplacental, fetal aorta, and umbilical artery blood flow velocity before 20 weeks and fetal

cerebral blood flow velocity before 28 weeks. Indices of blood flow velocity remain unchanged during the last half of pregnancy in the uteroplacental circulation and the fetal aorta. However, in the umbilical artery and cerebral circulation, increasing end-diastolic blood flow velocity with decreasing indices to term requires gestational age–adjusted reference data for the interpretation of individual observations. No consensus has yet been achieved in regard to the criteria for abnormality for these measures. The common criteria used in current studies are absent end-diastolic velocity, indices of blood flow velocity outside the 95% percentile, or >2 SD beyond the mean for the gestational age.

It has been proposed that abnormal uteroplacental waveforms may reflect the raised vascular resistance resulting from inadequate physiologic change in the spiral arteries, which is characteristic of hypertension in pregnancy.[89] Some evidence has been presented to support an association between abnormal uteroplacental waveforms and pregnancy-induced hypertension in selected pregnancies at risk. However, a matched cohort study demonstrated that patients with or without hypertension may have abnormal uteroplacental waveforms. These authors recommended that "greater understanding of the determinants of uteroplacental waveforms is required before this technique is used to critically effect management."[92]

There is evidence to indicate that insufficient maternal or fetal circulation may be an important factor in impaired fetal growth. Alterations of uteroplacental blood flow in association with growth retardation have been indirectly measured.[143] Villous perfusion has been demonstrated to be significantly reduced in idiopathic growth retardation.[144] Animal research has suggested that increased placental resistance is associated with reduced umbilical blood flow and impaired fetal growth.[145]

Abnormal uteroplacental waveforms have been observed in association with growth retardation in selected population studies. However, the association has not been consistent, and the sensitivity of this finding for growth retardation has been modest. There is little evidence that this can be used as a screening test in the general obstetric population.

Initial studies of the association of fetal aortic or umbilical artery blood flow velocity with growth retardation were encouraging. However, subsequent studies have demonstrated sensitivities in the order of 50%, with a large number of false-positive results. Two studies that examined the value of these observations as a routine screening test in a general obstetric population with a known prevalence of growth retardation have failed to demonstrate a predictive role for abnormal umbilical artery blood flow velocity for growth retardation. Studies of fetal hypoxia in the animal model[146, 147] have demonstrated a "brain-sparing" effect with increased cerebral blood flow velocity in the growth-retarded fetus. However, the findings in regard to cerebral blood flow velocity in growth retardation have not been consistent.

Antepartum alterations of fetal blood flow velocity in the uncomplicated pregnancy may be due to the recently demonstrated relationships with fetal blood gases. For example, it is proposed that the reduced blood flow per kilogram of body weight in the fetal aorta near term may reflect the redistribution of cardiac output in response to a relative degree of hypoxemia.[113] Similarly, it is proposed that the increased cerebral

blood flow velocity and decreased pulsatility index in the cerebral circulation are a response to the relative decrease of fetal oxygen tension.[115]

A test to predict biochemically determined fetal asphyxia would be of great value. Concurrent measures of antepartum fetal blood gas and acid-base status and fetal blood flow velocity in complicated pregnancies have been limited. In these circumstances, although the degree of abnormality of blood flow velocity parallels the severity of fetal blood gas compromise, random variations are observed.[114] Similarly, the data to date do not indicate that antepartum fetal blood flow velocity is a good predictor of intrapartum fetal asphyxia as expressed by umbilical artery blood gas measurement at delivery.

Using fetal blood flow velocity for predicting clinical fetal distress during labor has been proposed because there is evidence of an association between abnormal fetal blood flow velocity and clinical fetal distress in selected populations. However, the sensitivities are moderate and the positive predictive values are low. The examination of these measurements as a screening test in the general population suggests that maternal and fetal blood flow velocity before labor or in early labor has limited value as a screening measure for fetal distress.

One randomized clinical trial of the value of umbilical artery blood flow velocity as a component of fetal assessment has been reported.[148] The authors concluded that the availability of these data led to better decision-making with a lower incidence of clinical fetal destress and emergency cesarean section during labor. Normal umbilical artery blood flow velocity resulted in longer periods of nonintervention with less infant morbidity.

The importance of maternal and fetal blood flow to fetal growth and development is widely acknowledged. The opportunity to assess maternal and fetal blood flow and blood flow velocity with Doppler untrasonographic technology has been a significant development. Continuing research to refine these techniques and improve our understanding should remain a high priority.

However, no evidence has emerged during the last 5 years to support the routine use of maternal or fetal blood flow velocity determinations as a diagnostic test in the general obstetric population. The recommendation of the 1986 consensus conference is still valid. The use of Doppler assessment in pregnancy should be limited to the investigational setting.

Ultrasonography in the diagnosis of gynecologic disorders

J. Robert Willson, MD
Albuquerque, New Mexico

Ultrasonographic examination is being used with progressively greater frequency as an aid in diagnosis of gynecologic disorders but too often without consideration of whether information other than that obtained from clinical examination is needed and whether ultrasonography can supply it. The size, number, and position of pelvic masses and, in some instances, the type of tumor can be identified, but it is not often necessary when operation is clearly indicated. Ultrasonographic screening for diseases of the reproductive organs has been proposed, but its use for this purpose is limited and it is not cost-effective. It should be used as an adjunct to clinical diagnosis, not as a primary diagnostic procedure. (AM J OBSTET GYNECOL 1991;164:1064-71.)

Key words: Ultrasonographic diagnosis, gynecology, adnexal masses, ovarian cancer screening

The role of ultrasonographic examination in obstetrics is well defined, but its place in gynecology is less clear. The images produced by early equipment provided less information concerning the pelvic structures and their disorders than they did for the pregnant uterus and the fetus. Technologic improvements and increased experience in interpreting the images have made the evaluation of gynecologic disorders considerably more accurate than during early studies. Transvaginal ultrasonography provides clear images of the cervix, the uterus, the adnexa, and the cul-de-sac. A major disadvantage is that the effective focal zone of the transducer is short; masses that are beyond the range of the probe will not be clearly defined or will even be missed completely. In spite of the disadvantages transvaginal ultrasonography is clearly superior to transabdominal ultrasonography for evaluating the reproductive organs, and it can provide a visual image of the structures as they are being felt.

Early pregnancy and its complications

Since the advantages of ultrasonographic examination in the diagnosis of ectopic pregnancy, in determination of gestational age when dates are uncertain, in determination of the status of the embryo, and in evaluation of other complications of pregnancy are well known, they will not be discussed.[1, 2]

Gynecology

As image resolution has improved and with the introduction of transvaginal ultrasonography, ultrasonography is being used with greater frequency in nonpregnant women but too often without adequate consideration of whether additional information is needed, whether ultrasonographic examination can supply it, and whether it is cost-effective.

Pelvic masses. The experienced ultrasonographer can determine position, size, and gross morphology of adnexal masses in almost every instance, but it is more difficult to determine exact tumor type. Single or multiple clear cysts in an only slightly enlarged ovary are probably physiologic and not responsible for symptoms. Larger unilocular ones may be cystadenomas. Multiple small, bilateral clear cysts are characteristic of polycystic ovarian syndrome, but history and the hormone profile are better indicators of this disorder than is ultrasonography. Multiloculated cystadenomas, benign teratomas, endometriomas, and corpora lutea usually have characteristic appearances.[3]

It is possible to suspect malignancy on the basis of the ultrasonographic image,[4] but a definitive diagnosis cannot always be made. Benacerraf et al.[5] reported a 73% positive predictive value for malignancy in adnexal masses and a 91% negative predictive value for excluding malignancy. Benign tumors usually have sharp, well-defined margins and are more likely to be anechoic. Indistinct borders and the presence of a solid echo pattern suggest malignancy, and as echogenicity increases, so does the possibility of malignancy. Although ascites is usually present when a malignant tumor involves the peritoneum, there may be only a minimal amount of cul-de-sac fluid, or none at all, when the cancer is small and confined to the ovary or when there is only slight peritoneal involvement.

Although ovarian neoplasms and adnexal tumors may have typical ultrasonographic appearances, preoperative scanning of adnexal enlargements adds little but expense for the patient when there is a clear indication for operation. Too often, ultrasonographic ex-

Ultrasound panel, presented at the Ninth Annual Meeting of the American Gynecological and Obstetrical Society, Hot Springs, Virginia, September 6-8, 1990.

amination is ordered, simply because he or she palpates a pelvic mass. There is rarely a need for diagnostic imaging of any sort in women with obvious uterine leiomyomas and in those with unilateral adnexal masses ≥8 to 10 cm in diameter. These women can be operated on without further study.

Since one can usually suspect malignancy and anticipate the need for an extended operation by clinical evaluation alone, ultrasonographic examination should be an adjunctive rather than a primary diagnostic procedure in the study of adnexal masses. Color flow imaging may increase the accuracy when used for the diagnosis of cancers.[6]

Abnormal bleeding. A common cause of hypermenorrhea is the presence of submucous leiomyomas, which may not enlarge the uterus significantly and which may neither be felt with a curette nor be seen through a hysteroscope. Another cause is intramural myomas, which enlarge and distort the endometrial cavity. If the presence of myomas, their number, location, and size can be determined by ultrasonographic examination, an appropriate operative plan can be developed if myomectomy is being considered. Otherwise it is of limited value in these conditions; most therapeutic decisions can be made without it. Of course, ultrasonographic examination cannot replace biopsy to rule out malignancy as a cause of abnormal bleeding.

Pelvic pain. Ultrasonographic examination may indicate the cause of chronic pelvic pain, but in most instances the examination reveals no abnormalities. This is not surprising because of the many causes of chronic pelvic pain in which there is no anatomic change in the pelvic organs. Adhesions, which can be a factor in pain, may not be visible unless they distort the pelvic structures, the lesions of peritoneal endometriosis may be too small to be identified, and adenomyomas may not be detected. The fact that the examination reveals no source of the pain should not be completely reassuring.

Uterine cancer. Extension of cervical cancer into the parametrium and the depth of myometrial invasion of endometrial cancer can be determined by transvaginal ultrasonography, but the identification of extension to adjacent organs, lymph node involvement, and distant metastases is less accurate. Although thickness of the endometrium can be measured ultrasonographically and irregularities, fluid collections within the cavity, and endometrial polyps can be seen, biopsy is still essential in women with irregular bleeding, particularly those who are postmenopausal. A histologic diagnosis cannot be established, but ultrasonographically directed needle biopsy is a feasible procedure.

Adnexal infections. Ultrasonographic examination may be helpful in evaluating women thought to have acute salpingitis, particularly when there is a possibility that appendicitis may be causing the symptoms.[7, 8] It also may be helpful in diagnosing hydrosalpinx, pyosalpinx, and tuboovarian abscess and in monitoring response to antibiotic therapy. Pyosalpinges and tuboovarian abscesses can be drained and irrigated by ultrasonographically directed needle insertion.[9]

Reproductive endocrinology–infertility. In addition to follicle tracking in preparation for artificial insemination, follicle monitoring during ovulation induction, and ova retrieval, an infrequent use of ultrasonographic examination is to detect the occasional patient who is infertile because of the luteinized unruptured follicle syndrome. The hormone profile may be similar to that during normal ovulatory cycles, but the most informative noninvasive method of detecting failure to ovulate is serial ultrasonographic studies.

Postoperative complications. Ultrasonographic examination may provide important information in women with postoperative complications. Hematomas, abscesses, and unusual amounts of fluid blood within the peritoneal cavity can be identified. Abdominal wound dehiscence can be detected, as can hydroureter and hydronephrosis after ureteral injury.

Congenital müllerian anomalies. Fusion anomalies in the müllerian system can be identified by ultrasonography. With partial distal congenital vaginal aplasia and an intact uterus, for example, the blood-distended uterus, fallopian tubes, and proximal vagina can be seen and the extent of the defect determined.[10] Such examinations permit the surgeon to plan an appropriate operation. There should be no need for ultrasonographic examination in patients with imperforate hymen; the symptoms and the clinical appearance are characteristic. Uterine malformations, both during and in the absence of pregnancy, can be identified.

Screening. Ultrasonography is helpful in identifying or eliminating some disorders of the reproductive organs, but its role in screening has not been determined. If it does have an important screening potential, the most fruitful area might be in the detection of early ovarian cancer. Since most ovarian malignancies develop during the perimenopausal and postmenopausal phases of life, since most are advanced when diagnosed, and since the incidence increases with age, these are the women who should benefit most from screening.

Campbell et al.[11] performed 14,594 annual ultrasonographic screens in 5479 self-referred, asymptomatic women >44 years old. They identified five primary ovarian cancers, two at first screening and three at second screening; four were stage IA and one stage IB. They also identified an additional four patients with metastatic ovarian cancers.

Other than accuracy, an important factor in arriving at decisions on routine screening for ovarian cancer is cost-effectiveness. In the study of Campbell et al. a positive result was obtained in 338 screens of 326 women (2.3%); nine of these had either early primary

or metastatic ovarian cancer. This amounts to one abnormality in 432 screens and one cancer in 1621 screens. At an average charge of only $150 per screen (and this may well be low) the cost of diagnosing one ovarian abnormality would have been $64,800 and one ovarian cancer $243,150. In 1987 there were 5,744 million women aged 50 to 54 with life expectancies of about 30 years in the United States. If only half were screened only 10 times, the total number of screens would be 28.7 million, the total cost $4.3 billion, and the cost per ovarian cancer about $2.7 million.

Palpable postmenopausal ovaries. It is much easier to identify normal ovaries during reproductive life by both physical and ultrasonographic examination than the tiny, atrophic structures seen well after the menopause. Identification of both normal and abnormal ovaries should be more accurate with transvaginal ultrasonography than transabdominal ultrasonography, but atropic changes and constriction in the introitus and vagina may preclude the use of the vaginal probe.

Rulin and Preston[12] retrospectively compared ultrasonographic and operative findings in 150 postmenopausal women admitted for treatment of adnexal masses. Malignancy was found in only one of 32 ovaries that measured <5 cm in diameter. There were three invasive ovarian cancers, two borderline tumors, and one nonovarian cancer in 55 ovaries measuring between 5 and 10 cm, and there were 35 ovarian and five nonovarian cancers in 63 masses >10 cm in diameter. Goldstein et al.[13] identified 42 unilateral, unilocular cystic structures <5 cm in diameter in asymptomatic postmenopausal women by ultrasonographic examination. All 28 of the patients who underwent operation had benign ovarian or adnexal tumors. They proposed that serial ultrasonographic follow-up may be all that is necessary for women with small unilateral adnexal cysts that have none of the characteristic signs of malignancy. These findings suggest that operation is not always necessary when small ovarian enlargements are felt in postmenopausal women and that with more experience and with improvements in ultrasonographic technology it may become possible to determine which postmenopausal women with enlarged ovaries can be followed up safely.

Comment

Ultrasonographic examination is an important adjunct to clinical evaluation of the reproductive organs, but it is overused. There is no question of its value in identifying abnormal early pregnancy, in reproductive endocrinology and infertility, and for detecting and localizing pelvic masses, but other than these its role in gynecology is as yet unclear. Goldstein[14] has proposed that transvaginal ultrasonography be a routine part of every gynecologic examination and even that it be performed at each prenatal visit during early pregnancy. Clearly small, and often inconsequential, pelvic masses that are overlooked on physical examination will be identified by ultrasonographic examination. Conversely, the identification of small myomas, ovarian enlargements, and physiologic cysts may lead to increased patient concern and even to operations that might well be unnecessary. The cost of routine ultrasonographic examination does not justify its use.

As terrible a disease as ovarian cancer is, it plays a relatively small role as a cause of death in women. In 1986, 11,761 women >35 years old died of ovarian cancer, but 40,350 women in the same age group died of lung cancer, 39,865 of breast cancer, and 28,172 of colon and rectal cancer. It seems more logical to improve the availability and quality of health counseling and of preventive and early diagnostic services for these lesions and for cardiovascular and other potentially lethal disorders than to initiate ultrasonographic screening for ovarian cancer or for any other disorder of the reproductive organs.

Most reports on the accuracy of ultrasonographic examination in evaluating gynecologic lesions have been by experienced ultrasonologists with a background in diagnostic imaging. Obstetrician-gynecologists have usually learned ultrasonography from postgraduate courses and by the experience of interpreting their own films. It seems quite likely that the diagnoses made by the latter are less accurate than those made by diagnostic imaging professionals. Failure to diagnose obscure abnormalities or misinterpretation of the image opens the risk of legal action.[15] Ideally the acuity of obstetrician-gynecologists should be greater than that of ultrasonographers; the former have the advantage of having obtained a history and having performed pelvic examination whereas ultrasonographers study only the images. Diagnostic accuracy will undoubtedly improve in the future; ultrasonographic training in obstetric patients is now included in most residencies, but many lack comparable experience in imaging of gynecologic disorders. When expertise in this important adjunctive examination is expanded and when it is taught in departments of obstetrics-gynecology by obstetrician-gynecologists, most residents will become as competent in gynecologic ultrasonographic diagnosis as they now are in obstetrics.

Before the advent of ultrasonographic examination reasonably accurate diagnoses of early pregnancy and disorders of the reproductive organs were made by history and physical examination. Now one of the first thoughts of residents and many practicing obstetrician-gynecologists is to order ultrasonographic examination whenever pregnancy or an abnormality of any sort is suspected. Most such examinations could be avoided if physicians took the time necessary to obtain as much

historic information as possible, to examine patients skillfully, and to make diagnoses and establish treatment plans as though there were no backup alternative evaluative method. O'Brien et al.[16] found the preoperative clinical diagnosis to have been accurate in 67% of 52 women, whereas the ultrasonographic diagnosis was correct in only 42%. The diagnostic deficiencies of our residents stem from our not requiring that they continually improve their clinical diagnostic skills and from our permitting them to order diagnostic imaging and laboratory studies indiscriminately without considering whether they are necessary and how much additional information they will provide. Limiting the use of diagnostic imaging adds little risk for most patients and certainly reduces cost.

At the moment we would do well to accept the advice of two experienced ultrasonographers, Athey and Hadlock[17]: "Sonography of the female pelvis is most useful as an adjunct to the clinician's physical examination and should not be expected to provide histologic diagnoses. Once this is accepted by both sonologist and referring physician the sonologist can give a broad differential diagnosis without embarrassment and the referring physician will learn to appreciate the information gained and to interpret it in the light of the patient's clinical and physical findings." As both technology and experience in interpreting the films improve, ultrasonographic diagnoses will become more accurate and we will be able to identify lesions that are now overlooked. Even after this occurs, it is important that we insist that our residents develop and continually improve clinical diagnostic skills and learn to use ultrasonography as a secondary rather than a primary diagnostic tool.

Discussion

Secretary James R. Scott. By way of explanation, about 2 years ago the American Gynecological and Obstetrical Society had a retreat—the Council had a retreat and decided that we should take a role in deciding important issues in our specialty, and particularly areas such as new procedures and new technology, areas that are changing rapidly and may be confusing to all of us and particularly to physicians in private practice.

I think I really believe that one of my rules that applies to us in medicine is that nothing really works as well for you and me as it says in the literature and that there are many reasons for that. There really are.

As you know, there's almost an inherent bias in publishing. We all get enthusiastic about new things, and we want them to be positive. If you think about it, very few negative studies are published, or if it doesn't work for somebody else, he or she is really not going to publish it; retractions are rarely published.

That, along with sort of an entrepreneurial approach to medicine, with marketing, promotion, and so on, it's very easy to get enthusiastic about new techniques that may or may not be proved.

We wanted to set up a system for this program whereby we would take one topic that's important to us in our specialty and look at it in a more objective way or critique it; we're going to try to do this every year.

This year it was decided that we would take ultrasonography; specifically, we wanted people who are not ultrasonographers to look at the area. We picked what we hope, what we think, is a distinguished group that were given 1 year to look at this topic and give us a presentation that is not a position statement but is being published along with the rest of the articles from this meeting.

DR. PITKIN. The important part of this panel is the time for discussion and questions and comments from the floor, and it is now open for that purpose.

DR. FRANK CHERVENAK, New York, New York. Dr. Pitkin, that was an excellent conservative review of the value of ultrasonography in the diagnosis and management of fetal anomalies.

There is one point I hope we could clarify. We agree that ultrasonography is very valuable in the detection of many fetal anomalies; we also agree that this detection of anomalies can have very serious consequences in management options for the pregnant woman. In particular, in the absence of early detection of anomalies, she would not have the option of termination of pregnancy if those anomalies are diagnosed later in pregnancy or after birth.

In addition, for many other anomalies there are admittedly a few cases where fetal therapy and aggressive management, such as delivery in a tertiary center, can help.

It's also a fact that the ethical principle of respect for autonomy is a central principle in clinical obstetrics. Indeed, some authors would argue that it's the single most important ethical principle in the practice of obstetrics today. This principle has its most important application in clinical practice where medicine is a bit uncertain about the benefits and harms of diagnostic or therapeutic interventions.

The question I want to pose to you is, do you have any argument that would defeat an autonomy-based obligation of our profession to offer ultrasonographic examinations to the low-risk patient in clinical settings where quality—and I emphasize quality—ultrasonography is available? Offering such an option would fulfill the obligation of our profession to respect that autonomy. At the same time it would not force premature closure on this important debate and give us time to do the cost-benefit analysis and randomized studies that hopefully would allow us to come to a more definitive recommendation for or against routine ultrasonography.

DR. PITKIN. Those of you who have read Dr. Chervenak's recent article (Chervenak FA, McCullough LB, Chervenak JL. Prenatal informed consent for sonogram: An indication for obstetric ultrasonography. AM J OBSTET GYNECOL 1989;161:857-60), arguing on the basis of an ethical analysis for obstetric ultrasonography on patient request, will better understand the nature of his question.

Although perhaps everything is ethical in the final analysis, I would not cast this in the traditional ethical mode. Rather, I view it as a professional obligation and I personally have a difficult time whereby I am entirely unclear as to the proper action, saying to the patient, "You decide, because the issues are too complex for me to reach a conclusion."

I would not take issue with offering that service, but I would argue with its becoming the standard of practice before the important issue of cost-effectiveness has been dealt with.

DR. JAMES AIMAN, Milwaukee, Wisconsin. My question concerns screening ultrasonography. Accepting your figure of a 2% to 3% prevalence of anomalies, would you not expect a specificity of ultrasonography above 95%? Would you not achieve that specificity if you did nothing or merely palpated the abdomen, given the prevalence of anomalies?

DR. PITKIN. You are absolutely correct; specificity is 100 minus the prevalence.

DR. DAVID GRIMES, Los Angeles, California. I'll provide an epidemiologic footnote to Dr. Aiman's comment. There's a useful rule of thumb when one is interpreting the validity of a diagnostic test and that is that the sensitivity and specificity of a good test should add to at least 1.5 or 150%. The sensitivity and specificity of a very good test should add to at least 1.8; what we've seen in the past 45 minutes is that by that criterion, ultrasonography falls short for many indications.

DR. GEORGE D. WILBANKS, Chicago, Illinois. I certainly want to applaud Dr. Willson's comments about teaching the pelvic examination. I'm in the process of writing an article on the lost art of the pelvic examination, but I would not like to throw out the use of ultrasonography in screening for ovarian cancer and perhaps other diseases. I think the costs looked very big in this study, but as we are seeing in our residency program (ultrasound experience with the assisted reproduction program in endocrinology), residents are going to be very good with vaginal ultrasonography. It could be done very cheaply in the office setting by the obstetrician-gynecologist.

We also need to add the possibility of looking at endometrial cancer and ovarian cancer with the same screen. If we eliminate some of these sonographic examinations by the serum markers that we heard about today, such as CA 125 and interleukin 6, the costs should be more reasonable, but we should not eliminate ultrasonographic screening until we have more data.

DR. A. BRIAN LITTLE, Montreal, Quebec, Canada. I have two questions for Dr. Willson. The first one has to do with the pelvic examination. It seems to me that when chest roentgenography came along we suddenly found that the chest was quite different from what we anticipated with examination by stethoscope. I think it's particularly difficult in this day and age to teach people how to do pelvic examinations when so many people are immediately referring patients to ultrasonography without an examination.

So often we see women who have had ultrasonography and then are referred to the gynecologist, rather than the reverse. I have taken the position that it's probably not possible to teach anyone to do what some of us believe an examination should be after 20 or 30 years of experience without ultrasonography.

The second issue is that you didn't mention anything about vascularity, which ultrasonography can identify in pelvic masses. Masses can now be examined with Doppler techniques and an estimate of the degree of vascularity can suggest the presence of malignancy.

DR. WILLSON. I did mention color flow, which is vas-

cularity. As far as pelvic examination is concerned, I don't think we can throw out pelvic examination nor do I think we can substitute ultrasonography for pelvic examination.

Goldstein, for example, has suggested that every pelvic examination done in our offices should include an ultrasonographic examination and also that it should be done at every prenatal visit during early pregnancy. This, I think, is carrying it a bit too far.

I'm fully aware of the inaccuracies of pelvic examination; we don't find very small things, but the vast majority of small things that we miss are inconsequential. I've been working at pelvic examinations for several years, and I am no more completely accurate than anyone else. However, I don't think I need to substitute ultrasonography for my pelvic examinations, and I think residents can learn pelvic examination if we insist on it.

Dr. Timothy Johnson, Baltimore, Maryland. Dr. Pitkin, I think you passed over an issue that for some of us remains problematic—the political issue of ultrasonography and "turf." I see more and more other specialties getting involved with it—I recently heard of am emergency room doctor who wanted to get an ultrasound machine for the emergency room so he could do a vaginal probe ultrasonographic examination to rule out ectopic pregnancy before he sent the patient home. I suspect that, as Dr. Little just mentioned, more and more women are referred from physicians who use ultrasonography to monitor their patients, almost as a surrogate pelvic examination.

I guess it would be very useful for me if the distinguished members of the panel could tell me what their feeling is about the state of the art in 1990 with respect to our responsibility as obstetricians-gynecologists in performing and controlling the imaging modalities.

Dr. Pitkin. I'll respond first. I agree that the gynecologist's role in ultrasonography is a key one, but I do not feel that any medical specialty has a right to control it. Rather, I think it ought to be available for use by those who are experienced with it. The ultimate goal should be to help the patient rather than to exert political control.

Dr. Low. Our responsibility is to answer the questions that Dr. Pitkin posed. Is it safe? Does it work and is it cost-effective? If we do that, professionally speaking, we're creating the answers, which will ultimately lead to the practice.

As Dr. Pitkin pointed out, there is a tendency in health care for many things to be seriously misused for a while until the real truth comes home.

Dr. Pitkin. Dr. Willson, do you have a feeling about the turf issues?

Dr. Willson. I think the same thing ought to happen to gynecologic ultrasonography that happened to obstetric ultrasonography. It started with the ultrasonographers and gradually has become a service offered in departments of obstetrics-gynecology. If we do the same thing with gynecologic ultrasonography, then I think all concerned will end up with a better result—the patients, the residents who are learning, and ourselves.

Dr. Steven G. Gabbe, Columbus, Ohio. I want to congratulate the members of the panel. I think it's refreshing for those of us who spend a lot of time in darkened rooms looking at a lighted screen to evaluate these data objectively. I think the panel was able to do that.

A recent article from Finland (Saari-Kemppainen A, Karjalainen O, Ylostalo P, et al. Ultrasound screening and perinatal mortality: Controlled trial of systematic one-stage screening in pregnancy. Lancet 1990;1:387) showed, in a study involving >9000 pregnant women, an improvement in perinatal mortality, primarily because of the detection of malformations in women who did have a routine ultrasonographic examination. I would like to ask Dr. Pitkin to address a few of the other advantages espoused for routine ultrasonography; that would include improved dating of pregnancies. This would allow a more accurate interpretation of α-fetoprotein levels, which are obtained in most of our practices, earlier detection of twins, avoidance of hemorrhage from undetected or unrecognized placenta previa, and finally the psychologic benefits to the patient and her partner.

Do you have comments on these?

Dr. Pitkin. Although my topic was limited to screening for malformation, you've raised the broader matter of perinatal mortality in general. We must remember that old saw, "A difference, to be a difference, must make a difference." If ultrasonography detects lethal malformations early enough for these fetuses to be aborted, perinatal mortality rates should improve. I'm not familiar with the randomized trial that you mentioned, but the ones I do know have not demonstrated any clear improvement in perinatal outcome. Yes, twins can be diagnosed earlier; yes, gestational age can be fixed more accurately; yes, the placenta can be localized. But does it make any difference in outcome statistics? If not, I would argue that routine usage is difficult to support.

Dr. Robert Sokol, Detroit, Michigan. I would like to attempt to provide what might, perhaps, be considered a little balance to this discussion, at least from the perspective of a perinatologist.

Beginning with Doppler flow, I think it's fair to state that a clinical role, if any, for developing this technique is under intensive study. However, I believe that there is reasonable consensus that at this time it remains a research tool.

With regard to the views presented at this meeting concerning other ultrasonographic modalities, I think it's fair to state that they are far to the "right," in terms of the views of most maternal-fetal medicine subspecialists and prenatal geneticists, not to mention in terms of a reasonable interpretation of available studies and clinical experience.

Consider, for example, the statistical argument presented concerning predictability. Because congenital anomalies statistically are rare events, achieving im-

pressive sensitivity and specificity is difficult; indeed, guessing in the proportion of the prior probability typically will produce the best overall correct classification rate. For example, if an anomaly occurs at a rate of 1%, if you are faced with 100 pregnancies and you make 99 "no" guesses and 1 "yes" guess, you will be right 99% of the time. The problem is that your chance of being correct for a specific patient is only 1%, and missing an anomaly that could be detected easily during ultrasonographic examination is costly and clinically unacceptable. Sensitivity and specificity are not really the issue here.

Furthermore, our group has reported that visualization of fetal organs in the second trimester was distinctly limited in the mid-1980s, the period from which most of the studies in this review were derived. We will shortly report a very substantial improvement in ultrasonographic visualization of fetal organs, based, in part, on improved hardware.[2]

I suppose you could just forget trying to detect anomalies, but, in fact, being able to detect 20% to 30% of them is, for the individual clinician and patient, most assuredly of value. And I think our detection rate has improved and will continue to improve.

A brief final note as a follow-up to Dr. Little's comment on the gynecologic examination: Most of us who trained many years ago believe that we do very good pelvic examinations, but I believe that we could tell more by seeing than by feeling alone. While the technology is still under development, an ultrasonographic transducer that fits on the fingertip under the glove will soon be available. We will be able to visualize what we are feeling. Don't you think we'll be able to perform a much better pelvic examination? Time and technology march on.

DR. LITTLE. I have one more comment because I have to put money into ultrasonography like many other chairmen here. I'm enthusiastic but conservatively reluctant at the same time.

I wonder whether you're examining the wrong end point. In other words, your results are evaluated over a base number of 10,000 pregnancies. One of the biggest epidemiologic problems in obstetrics is to find an end point that will show a difference without considering large numbers. This is related to Dr. Sokol's comment that when you find a number of women who have these particular problems identified by early ultrasonography, a tremendous change takes place in the management of that pregnancy. When you find an abnormality, although not significant in your study, it is a very significant observation for that small number of patients.

I know that the overall cost makes a difference, but a positive result makes a big difference to that number. When you start thinking about this in terms of the rest of medicine, we're always trying to justify costs with the thousands of women or millions of women who have babies, other than the few who have an abnormal fetus. There's no question that the group with these abnormalities have a significant change in the way their pregnancies are managed and in the potential outcome after such a diagnosis. This could justify at least some extra cost.

DR. ALLEN P. KILLAM, Durham, North Carolina. I think the answer is that it is important to say that to make a difference, it has to make a difference. But I think if you're comparing standard obstetric care with any new interventions such as electronic fetal monitoring, we find that the risk to the patient is very low, and on a statistical basis to detect a real difference when the risk is very low requires huge numbers.

Yet we as practitioners are faced with a patient who says, "Shouldn't I have an ultrasound if I want it?" and you say, as an epidemiologist, "Well, we can't prove a cost-effective ratio." Yet if that patient wanted an ultrasonographic examination and you didn't do it and she were the very unusual patient to have a problem, then the hassle to us of not having offered it, even though we can't prove that statistically it's important, is so great that I think we end up, in practice, doing electronic fetal monitoring and using ultrasonography as a practical approach to avoid the very unusual case where it makes a difference, although it doesn't show up as statistically significant in our evaluations.

DR. PITKIN. Certainly, these kinds of considerations have influenced practice in a variety of ways over the years.

DR. DAVID COTTON, Houston, Texas. I saw you had a tremendous spread in the amount that physicians charge for an ultrasonographic examination. I would be interested in a comparison with what obstetricians charge for an initial physical examination and prenatal blood panel during pregnancy and what they charge for ultrasonography. In many states I would estimate the cost of a prenatal panel to be $100, and $50 to $75 for that initial physical examination.

My question is, would you feel more comfortable if the charges for ultrasonography were standardized in each community and if much lower rates were used? If that standardization occurred, would the cost-benefit analysis become favorable in your mind?

DR. PITKIN. Certainly, if you lower the cost and hold the benefit constant, then the cost-benefit ratio must decrease.

DR. COTTON. I guess what I am really asking is whether a physical examination of the fetus with ul-

trasonography is more cost-effective than a physical examination of the mother by her obstetrician?

DR. PITKIN. I don't know. Dr. Gant?

DR. NORMAN F. GANT, Dallas, Texas. This sort of reasoning just drives me insane. Here we've got an unbelievably technically difficult procedure to do, and we're talking about screening all the women in the United States with it. Even if it were the best screening technique today, which it isn't—and we've had evidence that it isn't—but even if it were, we couldn't implement it for another 20 years until we could train the people to do it and interpret it.

I think this is a form of mental gymnastics. What we're talking about here is whether someone could afford it. Let's lower it to $25. Well, if you lowered it to $25, you would still get the same result. You would have excellent people doing it who are publishing the articles, and then you would have the rank and file like me, who are frightened to turn on the machine because they're afraid they'll break it.

We have a technical skill here that in wonderful hands is not quite good enough, and that's what it is.

Make researching easier with the Ten-Year Cumulative Index (1978-1987) to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY

The Ten-Year Cumulative Index is a complete guide to more than 30,000 pages of original articles, case reports, letters, and editorials published in the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY from 1978 through 1987 (volumes 130 to 157). Numbering more than 800 pages, the Cumulative Index includes both a subject and an author index. This hard-cover volume is $64.50 ($69.00 international). Prices include shipping. *Payment must accompany all orders and must be in U.S. funds, drawn on a U.S. bank.*

Clinical Opinion

Sacrospinous fixation—Should this be performed at the time of vaginal hysterectomy?

Stephen H. Cruikshank, MD
Minneapolis, Minnesota

A sensible individualized approach should be applied to every patient undergoing transvaginal surgery for benign disease. This approach should attempt to correct every defect present in the pelvic supports. Uterovaginal prolapse is the result rather than the cause of genital prolapse. Not every vaginal hysterectomy should be treated like a cystocele-rectocele repair. Instead, every defect of the endopelvic fascial support should be evaluated in a patient both before and during surgery. As a result of these evaluations, more than just a hysterectomy and an anterior and posterior colporrhaphy may be performed. In a case in which a patient is found to have more than one defect at the time of examination, sacrospinous fixation of the vaginal apex at the time of transvaginal hysterectomy may be indicated. In the office, the patient can be examined in the supine and standing positions, both with and without Valsalva's maneuver, to determine if moderate to severe uterovaginal prolapse exists. Sacrospinous fixation should be performed in those cases as an adjunct to other steps taken to prevent posthysterectomy prolapse. (AM J OBSTET GYNECOL 1991;164:1072-6.)

Key words: Prophylaxis, uterovaginal prolapse, sacrospinous fixation

Vaginal vault prolapse is an infrequent but tragic complication that may occur after hysterectomy. Its incidence ranges from 0.2% to 43%. Both American and European literature are filled with descriptions of methods of repairing vault prolapse. Primarily as a result of the work of Nichols and Randall[1, 2] in the United States, the use of sacrospinous fixation to correct this condition has had a resurgence in our country. Others have stated that sacrospinous fixation should be used only for therapy of posthysterectomy vault prolapse.

The word *prophylactic* as it pertains to the use of sacrospinous fixation at the time of hysterectomy has been misunderstood by many. According to *Webster's Dictionary, prophylactic* means to prevent or to ward off. This is indeed what we would like to do when it comes to posthysterectomy prolapse—prevent or ward off this complication. The word *prophylactic* does not mean *routine*. If we examine a patient who has a defect of the uterine ligaments, as well as other defects in the vaginal supportive structures, we should think about adding an additional measure to prevent posthysterectomy prolapse.

This article recommends the use of sacrospinous fixation at the time of hysterectomy as an adjunctive measure in those patients who are at risk for vault prolapse. A clinical definition of patients at risk for future vault prolapse is provided. Also described is a method of attaching the uterosacral cardinal ligaments to the vaginal membrane to help prevent vault prolapse in patients who undergo hysterectomy. In addition, material relevant to sacrospinous fixation at the time of hysterectomy is described with illustrations.

It is important that physicians who treat patients with pelvic floor relaxation consider each aspect of the supportive structures of the pelvic floor. I think that it is of value to keep this in mind when the patient is evaluated in the office. An excellent history and physical examination with the patient in erect and supine positions are of utmost importance. After the physician has determined whether the patient has genital relaxation, an attempt should be made to identify in which anterior-posterior area the defect occurs and then the repair can be planned. Uterine prolapse is not the cause of genital prolapse; it is the result. Are we really sure what causes anterior wall relaxation, posterior wall relaxation, or an enterocele that is the result of genital prolapse? I don't think so, but I think that we should do everything that is therapeutically available to prevent the hazards of not totally repairing all defects at the time of hysterectomy. All relaxations should not be treated as cystocele-rectocele.[3]

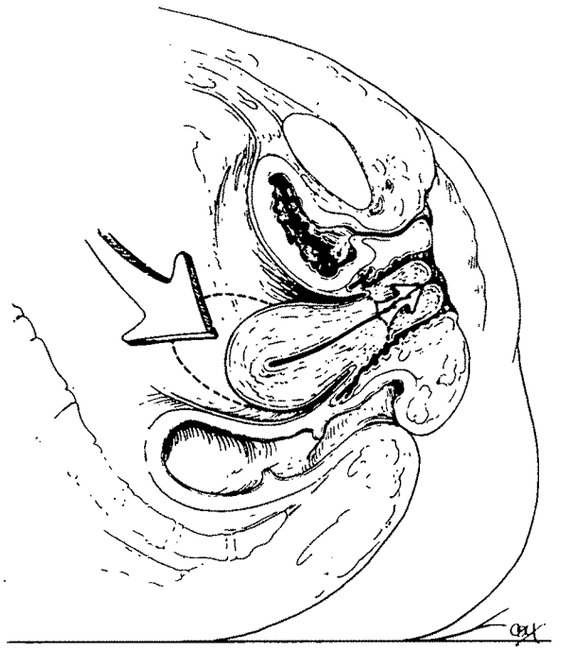

Fig. 1. Moderate uterovaginal prolapse. (From Cruikshank SH, Cox DW. Sacrospinous fixation at the time of transvaginal hysterectomy. AM J OBSTET GYNECOL 1990;162:1611-9.)

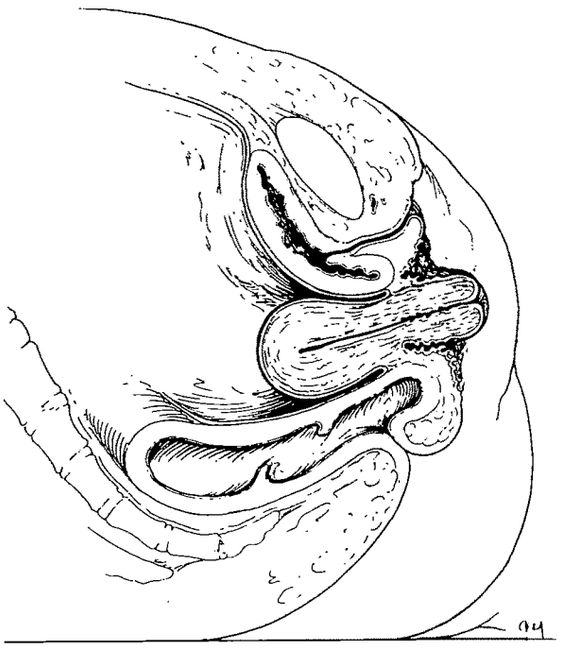

Fig. 2. Severe uterovaginal prolapse. (From Cruikshank SH, Cox DW. Sacrospinous fixation at the time of transvaginal hysterectomy. AM J OBSTET GYNECOL 1990;162:1611-9.)

Genital prolapse (uterine-vaginal prolapse, cystocele, rectocele, enterocele) represents a disorder of the pelvic support. We must determine whether the prolapse was caused by childbirth, pelvic trauma, or stretching or laceration of the connective tissue of the vagina or by the more common causes, postmenopausal atrophy and attenuation. Some authors think that genital prolapse may result from a neuropathy or a congenital defect of the elastic tissue of the pelvic supportive structures. Last but not least, genital prolapse can be caused or exacerbated by chronically increased abdominal pressure associated with obesity, masses, chronic respiratory diseases, or occupational hazards.

The symptoms of uterovaginal prolapse include bulging with sitting or walking, ineffective control of or difficulty with urination or defecation (these patients are predisposed to urinary tract infections), irregular spotting or discharge associated with ulcerations, interference with coitus, or increased pelvic pressure or backache. When we see patients with these problems in the office for the initial evaluation, it is important to determine how to treat these patients surgically. Our objective is to restore the abnormal state to its normal anatomic position, to restore function, and to perform the appropriate procedure that results in the least chance of recurrence of the problem. When more conservative treatments such as exercise, estrogen therapy, and the use of pessaries in certain patients fail, transvaginal[2, 3] or transabdominal[4] surgical treatment of genital prolapse is indicated. We must also look for other defects and repair them at the time of surgery. If patients present with moderate or severe uterovaginal prolapse or procidentia, a sacrospinous fixation can be added at the close of hysterectomy and any other plastic repairs that replace the vagina in its near-horizontal position above the levator ani.

We should also look for defects in the endopelvic fascia and the genital supportive structures of patients who meet the criteria for transvaginal hysterectomy and whose primary indication for hysterectomy is other than uterovaginal prolapse. If a patient presents with moderate or severe *uterovaginal* prolapse or symptomatic pelvic relaxation, she may fulfill the criteria for having adjunctive sacrospinous fixation. *Moderate uterovaginal prolapse* (not uterine, but uterovaginal) is defined as the presentation of the cervix past the midportion of the vagina or to the introitus as a result of Valsalva's maneuver (Fig. 1). *Severe uterovaginal prolapse* is defined as the presentation of the cervix past the introitus either with or without Valsalva's maneuver (Fig. 2). If the uterosacral-cardinal ligament complex is found to be totally lax (surgically weak) or nonexistent, as it is in many cases of procidentia, then these structures will be unavailable to shorten or attach for support. An attempt should be made, however, to attach these ligaments in addition to performing sacrospinous fixation.

Traditionally, sacrospinous fixation has been regarded as a therapeutic tool to be used only for the repair of vaginal vault prolapse. However, I believe that

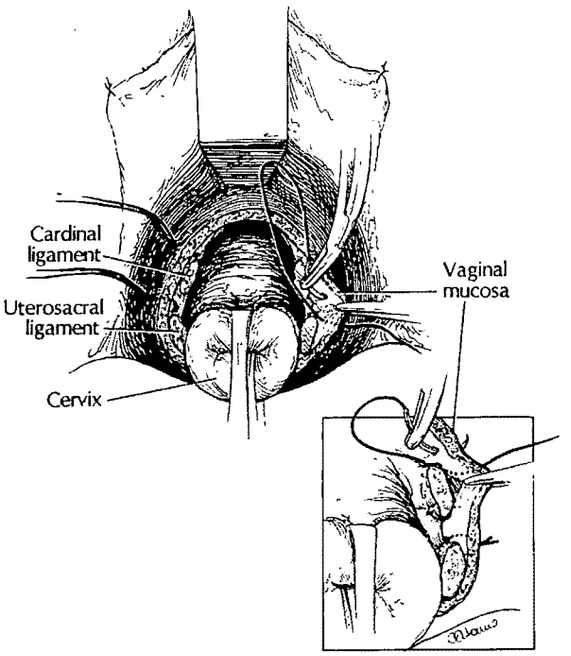

Fig. 3. Attaching uterosacral-cardinal ligaments to vaginal membrane. (From Cruikshank SH. Preventing posthysterectomy vaginal vault prolapse and enterocele during vaginal hysterectomy. AM J OBSTET GYNECOL 1987;156:1433-40.)

this procedure also may be used as a preventive measure in those patients who are at risk for posthysterectomy prolapse. Not every patient undergoing vaginal hysterectomy is a candidate for sacrospinous fixation. If a loss of the pelvic supportive structures (uterosacral-cardinal ligament complex) is noted at the time of hysterectomy, then an attempt to use their remnants should be made. However, sacrospinous fixation as an adjunct will prevent further vault prolapse. In *Vaginal Surgery,* 3rd edition, Nichols[1] states that in the absence of strong pelvic support a sacrospinous colpopexy is easy to perform after vaginal hysterectomy.

When a patient has been evaluated and has been found to have moderate to severe uterovaginal prolapse or procidentia, other defects in the vaginal wall can be identified. If necessary, anterior colporrhaphy, posterior colporrhaphy, and enterocele repair (or a procedure to prevent enterocele) can be performed. At the close of anterior colporrhaphy, the vaginal apex can be pulled toward the introitus with an Allis clamp. If the apex comes down to the introitus or past the introitus, the patient is probably at risk for future posthysterectomy vaginal prolapse. This patient should undergo sacrospinous fixation at that time, after which any other plastic repairs can be performed and the sacrospinous stitch can be tied to secure the apex against the sacrospinous ligament.

I like to attach the uterosacral and cardinal ligaments to the angles of the vaginal membrane in all patients undergoing transvaginal hysterectomy (Fig. 3).[5] This should be done as an initial step after the anterior and posterior colpotomy. If the structures are not too attenuated or lax and do not need shortening, this step can be undertaken immediately and will accomplish three goals: (1) It will help prevent posthysterectomy prolapse; (2) it will tie the angles of the vagina, which is a common site of postoperative bleeding; (3) it will prevent the physician from inadvertently cutting the sutures without having attached them to the vaginal membrane at the end of the operation. Many times these structures are too lax and need to be shortened and reattached after uterine extirpation. If the vaginal apex still appears at the introitus, then a sacrospinous fixation can be undertaken. The ligament fixation procedure is performed as follows: The posterior wall is opened to the apex. This is full-thickness vaginal membrane. The incision should be through the endopelvic fascia, which places the operator in the rectovaginal space. This space is dissected by the operator to the level of the ischial spines; however, the ischial spines and the coccygeus muscle cannot be identified at this time because the descending rectal septum must be perforated. At the time the descending rectal pillar is perforated, the pararectal space is opened (Fig. 4). The ischial spine and the coccygeus muscle–sacrospinous ligament complex are palpated and visually identified via additional blunt or sharp dissection. Number 2 Vicryl sutures are then placed by direct visualization through the ligament approximately 2 to 3 cm medial to the ischial spine. These sutures are held and left untied until any additional reconstructive procedures are completed. When the other procedures have been completed, the sacrospinous ligament fixation is carried out via both the safety stitches and pulley stitches (Fig. 5).

To date there is only one moderate-sized series that documents the usefulness of the sacrospinous fixation as an adjunct to transvaginal hysterectomy.[6] In that study transvaginal hysterectomy was accomplished in 135 consecutive patients. Forty-eight adjunctive sacrospinous fixations of the vagina were carried out in these same patients, who had presented with primary complaints plus additional uterovaginal–symptomatic outlet relaxation. There were no cases of injury to the rectum, nerves, or bladder in any of the 48 cases. Significant bleeding from the perirectal veins occurred in only two cases, but the bleeding stopped with pressure and no sequelae resulted.

In this same study the morbidity and complications were low. All patients received prophylactic cephalosporin antibiotics. Ninety-two percent of the 48 patients remained afebrile throughout the postoperative course. Of the four patients with febrile morbidity, three had urinary tract infection and one had no cause found. The average blood loss for all the procedures done was 290 ml; the average blood loss for sacrospi-

nous fixation was 100 ml. The average time for the entire operation, which was performed in a teaching setting, was 2 hours 20 minutes, and the average time for the sacrospinous fixation was 18.5 minutes. In this study some minor complications had resolved by the time the patient returned for the 6-week postoperative checkup. Four patients who underwent anterior colporrhaphy were unable to urinate before discharge from the hospital and were sent home with Foley catheters in place. All four patients were able to subsequently urinate. Two patients had transient stress incontinence from the sacrospinous procedure, but this complication also resolved in both cases. Twenty patients had right buttock pain that resulted from adequate dissection in the perirectal space and direct visualization of the sacrospinous ligament. No patients had resultant sciatica or neuropathies as a result of the procedure. All 20 of these patients had spontaneous resolution of buttock pain by the 6-week checkup. All patients underwent follow-up for 1 year 6 months to 3 years 8 months after surgery; posthysterectomy vault prolapse occurred in only one case. All patients were examined in both standing and supine positions at the 6-week postoperative visit and were asked to perform Valsalva's maneuver so that partial prolapses or missed enteroceles could be identified. The mean follow-up time of this study has now been more than 3 years.

In this same study 25 patients had anterior colporrhaphy to correct urinary stress incontinence, symptomatic anterior vaginal wall relaxation, or both. Eighteen patients had posterior colporrhaphy in addition to an anterior repair. Five patients had enterocele repair, and seven additional patients had posterior colporrhaphy only. Only one patient had a recurrent posthysterectomy vault prolapse.

Comment

There have been many previously described methods that use the pelvic supportive structures (cardinal-uterosacral ligament complex) to help prevent posthysterectomy vault prolapse. These methods hold the

vagina in its horizontal position above the levator ani; however, if these supportive structures are not present, the vaginal apex is still at risk for prolapse. In this study all 48 patients had the apex drawn past the introitus after hysterectomy and plastic repair of the anterior wall. I feel that it is appropriate during transvaginal hysterectomy to support the vagina in its normal anatomic position. Moreover, if moderate or severe uterovaginal prolapse exists, either as a main indication or as a secondary diagnosis, it can be corrected with sacrospinous fixation to prevent future complications and additional procedures for the patient. Sacrospinous fixation is not to be performed universally at the time of hysterectomy. In the study cited, only 35% of the 135 patients who underwent vaginal hysterectomy fulfilled the prerequisites for sacrospinous fixation of the vaginal vault. I feel this is an appropriate adjunctive or prophylactic procedure if strict criteria are met: (1) total laxity of the uterosacral-cardinal ligament complex, (2) total procidentia at the time of hysterectomy, (3) moderate to severe laxity of the supportive structures and the ability to pull the vaginal apex to or past the introitus after hysterectomy and other plastic repairs have been performed.

Various principles of vaginal fixation are recognized today. I think that it is paramount that we note the laxity of any supporting structures and that we attempt to repair them at the initial operation, which affords the best chance of success. Transvaginal hysterectomy is a good method of preventing future vaginal prolapse. It seems feasible to add sacrospinous fixation to vaginal hysterectomy in patients who present with moderate to severe uterovaginal descensus and loss of pelvic support. Not every patient undergoing vaginal hysterectomy is a candidate for sacrospinous fixation. The procedure carries minimal morbidity, it supports the vaginal apex, and it provides pelvic surgeons with an additional adjunctive or prophylactic measure against posthysterectomy prolapse.

Carrier screening for cystic fibrosis: Implications for obstetric and gynecologic practice

Sherman Elias, MD,[a] George J. Annas, JD, MPH,[b] and Joe Leigh Simpson, MD[a]
Memphis, Tennessee, and Boston, Massachusetts

Cystic fibrosis, which is one of the most common autosomal recessive disorders, has a carrier frequency of approximately 1 in 25 among whites in the United States. In this population approximately 75% of the mutations in patients with cystic fibrosis correspond to a 3 base pair deletion that results in the loss of a phenylalanine residue at amino acid position 508 (designated ΔF_{508}) from the coding region of the cystic fibrosis gene. Currently, only about half of the couples at risk can be identified as cystic fibrosis carriers. We support conclusions of the National Institutes of Health Workshop on Population Screening for the Cystic Fibrosis Gene, which state that carrier testing should be offered to all individuals or couples with a family history of cystic fibrosis. Good science and solid educational and counseling strategies must be in place before screening for cystic fibrosis is routinely offered to those with a negative family history. Pilot programs that investigate research questions in the delivery of population screening for cystic fibrosis carriers are urgently needed. (AM J OBSTET GYNECOL 1991;164:1077-83.)

Key words: Cystic fibrosis screening, ΔF_{508} mutation

Physicians and their patients face a continually increasing array of diagnostic tests that demand decisions regarding clinical use. Unfortunately, the decision to offer a new test has in the past sometimes been driven by the desire to avoid a potential lawsuit for not testing (defensive medicine). The medical profession is currently faced with another new screening test that has been heralded with banner headlines in the nation's newspapers—carrier screening for cystic fibrosis. Which position should obstetricians take regarding the use of this test in their practices, and what should they tell their patients about it? This article summarizes the current state-of-the-art in medical testing and suggests how the nature of the test and the applicability and reliability of its results lead to conclusions that support its limited use in current clinical practice.

Cystic fibrosis is the most common life-threatening autosomal recessive disease among North American whites of European ancestry. In this population the disease frequency is about 1 in 2500 live births, and the calculated carrier frequency is about 1 in 25 individuals.[1] Common clinical manifestations of cystic fibrosis include meconium ileus, chronic obstructive pulmonary disease that results in bronchiectasis and respiratory failure, pancreatic exocrine insufficiency with steatorrhea, liver cirrhosis, and failure to thrive.[1] The clinical course of cystic fibrosis is highly variable and ranges from death in the neonatal period as result of complications of meconium ileus to protracted survival into the fifth and sixth decade. Approximately half of patients with cystic fibrosis can be expected to live to age 26 or longer.[1]

Until the mid-1980s, families known to be at increased risk for cystic fibrosis could be offered only genetic counseling that used calculated risks that were based on mendelian inheritance. In recent years, however, a number of important advances have been made. First, microvillar-intestinal-enzyme levels have proved to be decreased in the amniotic fluid of women carrying fetuses affected with cystic fibrosis, although the sensitivity and specificity of this assay were less than optimal.[2] Later, use of polymorphic deoxyribonucleic acid (DNA) markers closely linked to the cystic fibrosis gene locus on chromosome 7 made prenatal diagnosis possible, with the use of either amniotic fluid cells or chorionic villi, with a very high degree of accuracy for most couples; however, DNA from the previously affected relative was necessary.[3, 4] For close relatives of cystic fibrosis patients, carrier testing by DNA linkage studies also could be provided with a high degree of accuracy.[5]

Within the past year, the cystic fibrosis gene has been cloned and sequenced.[6-8] The protein presumed to be encoded by the cystic fibrosis gene has been named the cystic fibrosis transmembrane conductance regulator and is believed to be a membrane-bound transport molecule. However, the manner by which cystic fibrosis

transmembrane conductance regulator is involved in regulating ion conductance across the apical membrane of epithelial cells is unclear.[7] Nonetheless, identification and characterization of the cystic fibrosis gene offer strategies for increasing the accuracy of cystic fibrosis prenatal diagnosis beyond that possible by linkage analysis alone.

Genetics

In the United States white population of European ancestry (excluding Ashkenazic Jews and Hispanics), about 75% of the mutations in cystic fibrosis patients correspond to a three base pair deletion. This deletion results in the loss of a phenylalanine residue at amino acid position 508 (designated ΔF_{508}) from amino acid coding region 1480 of the cystic fibrosis gene.* From a study of 200 non-Ashkenazic white families in which a family member had cystic fibrosis, Lemna et al.[9] determined that 58.2% of individuals affected with cystic fibrosis were homozygous for the ΔF_{508} mutation, 33.7% were heterozygous for this mutation, and 8.0% were homozygous for the absence of this mutation. The frequency of the ΔF_{508} mutation varies among different ethnic groups. For example, in Spanish and Italian populations the mutation accounts for only 49% and 43% of cystic fibrosis mutations, respectively.[10] The 3 base pair deletion appears to be much less common in the U.S. Ashkenazic Jewish population, in whom approximately 30% of cystic fibrosis mutations occur.[9] The frequency of cystic fibrosis in black Americans is about 1 in 17,000 births[11]; however, the proportion of cystic fibrosis cases that result from the ΔF_{508} mutation in this population has not yet been established.

If a 1 in 2500 frequency of cystic fibrosis in the U.S. non-Ashkenazic white population is assumed, the likelihood of detecting an individual as a cystic fibrosis carrier can be determined from the various mutation detection rates (Table I). If, for example, 75% of cystic fibrosis mutations are detectable by DNA analysis, the likelihood that an individual with a negative test is a carrier is reduced from an a priori risk of 1 in 25 to a new risk of 1 in 99. If the DNA of one parent is positive for a mutation but the DNA of the other parent is negative, the risk that the couple will have a child with cystic fibrosis is (1, or known heterozygote)(1/99)(1/4), or 1/396. If DNA of neither parent tests positive for a mutation, the risk of having a child with cystic fibrosis is (1/99)(1/99)(1/4), or about 1/39,200. Contemplating population-based screening necessitates deriving the likelihood of detecting couples who are actually cystic fibrosis carriers; this can be calculated as a function of the mutation detection rate (Table II). At a 75% mutation detection rate, for example, both partners will be identified as carriers in 56.3% of the cases; in 37.5% of couples only one of the partners will be identified as a cystic fibrosis carrier; in 6.2% neither partner will be identified as a cystic fibrosis carrier.[9]

A number of clinical scenarios can be envisioned for the United States non-Ashkenazic population, if a cystic fibrosis mutation detection rate of 75% is assumed.

Previous child affected with cystic fibrosis. *Both parents are heterozygous for ΔF_{508}, with or without the availability of the affected child.* Couples who have a child with cystic fibrosis have a 1 in 4 recurrence risk in each subsequent pregnancy, unless there is the rare occurrence of a new mutation. If a child with cystic fibrosis is homozygous for the ΔF_{508} mutation and the parents are heterozygous for the same mutation, prenatal diagnosis by direct mutation analysis with the use of either chorionic villi or amniotic fluid cells is the method of choice in terms of speed and reliability. Identification of such a child can be expected in 0.75×0.75, or 56.3% of cases. The ΔF_{508} mutation analysis provides almost 100% accuracy in identifying an affected fetus and does not require DNA from a previously affected child.

Parents have discrepant mutations in the cystic fibrosis gene; DNA from the affected child is available. The affected child could be a compound heterozygote for the ΔF_{508} mutation; i.e., one parent could contribute a chromosome 7 with the ΔF_{508} mutation and the other parent could contribute a chromosome 7 with a different mutation in the cystic fibrosis gene. A child also could be affected with cystic fibrosis as a result of each parent's contributing a chromosome 7 with a mutation in the cystic fibrosis gene other than the ΔF_{508} mutation. In both situations prenatal diagnosis with a high degree of accuracy can still be offered if DNA from the affected child is available. A combination of ΔF_{508} mutation analysis and restriction fragment length polymorphism linkage analysis is used in the former circumstance, whereas linkage analysis alone is used in the latter.

Parents have discrepant mutations in the cystic fibrosis gene; DNA from the affected child is not available. If one parent carries the ΔF_{508} mutation and the other parent does not, fetal DNA can be analyzed to determine if the fetus did or did not inherit the mutation from the ΔF_{508} carrier parent. If not, the fetus is unaffected. If the ΔF_{508} carrier parent *did* transmit the cystic fibrosis gene to the fetus, there is a 1 in 2 risk that the fetus is affected. Under these circumstances amniotic fluid microvillar-intestinal-enzyme analysis would be particularly useful in predicting fetal cystic fibrosis status. Enzyme analysis

*In the context of this article, the term *mutation analysis* refers to abnormalities of the cystic fibrosis gene itself, which is demonstrable by DNA analysis (e.g., the ΔF_{508} mutation). By contrast, the term *linkage analysis* refers to restriction fragment length polymorphism DNA markers that are linked to the cystic fibrosis gene but usually are not within the actual gene. Thus restriction fragment length polymorphism analysis only indirectly provides information concerning the presence or absence of the cystic fibrosis mutation.

carries an estimated false-positive rate of 2% and a false-negative rate of 8%.[9]

Close relative with cystic fibrosis. An unaffected sib of an individual with cystic fibrosis has a 2 in 3 likelihood of being a cystic fibrosis heterozygote and a 1 in 3 likelihood of being homozygous normal. An uncle or aunt of an individual with cystic fibrosis has a 1 in 2 likelihood of being a cystic fibrosis heterozygote and a 1 in 2 likelihood of being homozygous normal. A first cousin of an individual with cystic fibrosis has a 1 in 4 likelihood of being a cystic fibrosis heterozygote and a 3 in 4 likelihood of being homozygous normal. Thus, if an individual has a close relative with cystic fibrosis (sib, niece, uncle, or first cousin), that individual should be offered carrier testing with mutation analysis or linkage analysis. If the parent who has a close relative with cystic fibrosis is indeed found to be a carrier, mutation analysis of the spouse is indicated. If both parents are determined to be carriers, their risk for having offspring with cystic fibrosis is 1 in 4; prenatal diagnosis would be appropriate. If one parent carries the ΔF_{508} (presumably the high-risk parent) and the other parent does not carry the ΔF_{508} mutation, the couple's risk for having a child with cystic fibrosis is 1 in 396. If the ΔF_{508} carrier parent *did* transmit the cystic fibrosis gene to the fetus, there is still only a 1 in 198 risk that the fetus is affected. Under these circumstances prenatal diagnosis could not provide an unequivocal determination of fetal status. Even if microvillus intestinal enzyme analysis were used, on the basis of known false-positive (2%) and false-negative (8%) rates for this test,[9] Bayesian calculations show that an abnormal result would yield a 19% probability that the fetus is affected. Thus there is an 81% probability that microvillus intestinal enzyme analysis would represent a false-positive result.

Population-based cystic fibrosis carrier screening. In the United States non-Ashkenazic white population about 75% of heterozygotes have the ΔF_{508} mutation. Therefore, as shown in Table II, only about 50% of those couples in which both partners are cystic fibrosis carriers can now be identified by screening for the ΔF_{508} mutation. If additional cystic fibrosis mutations were discovered and if, for example, 95% of carriers could be detected, then 90% of couples at risk would be identified (Table II). It was initially hoped that the remaining 25% of cystic fibrosis mutations would be relatively few in number so that most, if not all, cystic fibrosis carriers could be identified efficiently.[1] Unfortunately, this has not proved to be the case; more than 20 additional mutations have already been identified, each of which is individually rare. Thus, if population-based cystic fibrosis screening is undertaken, one partner in about 1 in 15 couples would be identified as a carrier of the ΔF_{508} mutation and the other partner would not carry this mutation. However, failure of the other partner to have the ΔF_{508} mutation does not exclude that partner's being a cystic fibrosis carrier for a different cystic fibrosis mutation but rather merely reduces the likelihood from 1 in 25 to 1 in 99 (Table I). In these couples the risk of having a child with cystic fibrosis is about 1 in 400, but prenatal diagnosis cannot presently provide an unequivocal determination of fetal cystic fibrosis status even with the combination of amniotic fluid microvillus intestinal enzyme testing and restriction fragment length polymorphism linkage analysis.

Table I. Cystic fibrosis–related risks after mutation analysis for carrier status

Cystic fibrosis mutations detectable (%)	*Carrier risk for person with negative test*	*Risk of cystic fibrosis in offspring of couples tested*	
		One parent positive	*Neither parent positive*
0	1/25.5	NA	1/2,500
70	1/82.7	1/331	1/27,400
75	1/99	1/396	1/39,200
80	1/124	1/494	1/61,000
85	1/165	1/661	1/109,200

Public policy for carrier screening

In March 1990 the National Institutes of Health Workshop on Population Screening for the Cystic Fibrosis Gene[12] was convened to make suggestions about the introduction of cystic fibrosis screening into medical practice. The group concluded that pilot programs to investigate research questions in the delivery of population screening for cystic fibrosis are "urgently needed." The National Institutes of Health panel merely listed the following five guidelines that are already widely accepted as applicable to any widespread

population screening. We believe that each merits elaboration in the context of cystic fibrosis screening.

Screening should be voluntary and confidentiality must be assured. The National Academy of Sciences recommended in 1975 that "participation in a genetic screening program should not be mandatory by law, but should be left to the discretion of the person to be tested or, if a minor, of the parents or legal guardian."[13] The President's Commission on Bioethics strongly endorsed this recommendation and noted: "Some individuals are likely to choose not be screened for cystic fibrosis, and their ability to make that choice must be safeguarded."[14]

Confidentiality enhances the trust implicit in the doctor-patient relationship, and medical information should not be disclosed to third parties without informed consent. The President's Commission stated: "Because of the potential for misuse as well as unintended social or economic injury, information from genetic testing should be given to people such as insurers or employers only with the explicit consent of the person screened."[14] We can foresee no circumstances under which confidentiality should be breached in cystic fibrosis carrier screening programs. Even if an individual who is identified as a carrier refuses to allow this information to be conveyed to a sibling, the a priori risk of that sibling's having a child with cystic fibrosis is $<1\%$.

Screening requires informed consent. Providers of screening services have an obligation to assure that adequate education and counseling are included in the program. Autonomy is an illusion if the individual does not understand to what he or she is being asked to consent. Accordingly, there is a need to develop prescreening educational material that adequately explains, in lay terms, the benefits of screening, as well as the limitations and risks of screening, such as loss of insurability and adverse psychosocial effects. This information must, of course, be made available to the individual *before* consent for screening is sought. In addition, professional counseling about the significance of positive screening results and reproductive options must be available when results are made known to the individual.

The goal of genetic screening and counseling is "to make people into informed decision makers about their genetic constitution, to the extent it is relevant to choices about their own well-being or that of their family."[14] The success of population-based cystic fibrosis carrier screening will depend on the practicing medical community's becoming knowledgeable and supportive of the entire process, as well as on educating and involving the public. Before population carrier screening begins, informational campaigns at national and local levels must be in place to educate the public about the objectives and availability of screening. It has been estimated that if 3 million couples per year who contemplate having children were screened and if those couples were counseled for 10 minutes before the test and at-risk couples were counseled for an hour after the test, 651,000 hours of counseling would be required to meet the screening-generated demand.[15] Cystic fibrosis screening of this limited population would require more than 17 weeks per year from each of the approximately 1000 certified genetic counselors and clinical geneticists.[15] The alternative is that primary providers such as obstetrician-gynecologists have the requisite knowledge and counseling skills.

As the number of possible genetic screening tests proliferates, it will be necessary to devise new strategies to educate and help individuals to decide to use specific screening tests. These tests may ultimately involve such interventions as interactive videotapes that can be played at home and in physician's waiting rooms, as well as the use of specially trained nonphysician counselors in clinics and schools.

The National Institutes of Health panel concluded that the current difficulties with cystic fibrosis screening (i.e., only 75% of carriers are detectable) "would be substantially reduced if testing could detect at least 90 to 95% of carriers." Although there is certainly a degree of arbitrariness about any cutoff point for inclusive detection, this degree of inclusiveness (90% to 95%) seems reasonable if one of the major benefits of screening is excluding individuals from the "at-risk" category. First, without a screening process that meets this degree of inclusiveness, the amount of reassurance one can provide to a couple is substantially reduced. Second, the result may be to foster both fear and stigmatization. Third, at a detection rate of 75%, the costs of population screening are very high as compared with the benefits. Wilfond and Fost,[15] for example, estimate that at that rate 11,100 couples would have to be screened to detect 10 couples at risk. If 80% of those families chose prenatal diagnosis, two (25%) would be expected to have an affected fetus. If half (one) of those families with an affected fetus terminate the pregnancy, one of two cystic fibrosis births would be avoided. At $200 for screening and counseling per couple, the cost of avoiding one cystic fibrosis birth in this scenario is $2.2 million. Even if the detection rate were increased to 95% and the cost were decreased to $70 per couple, the cost would still be $1 million per cystic fibrosis birth avoided, and this does not take into account costs incurred by effects that result from error or stigmatization.[15]

On the other hand, individual members of the public may feel that a lower cutoff (namely, 57%) is acceptable for individual testing (versus population screening) and may reject the National Institutes of Health panel's perhaps somewhat paternalistic conclusion. A flexible ap-

proach thus seems prudent and reasonable at this point. If a highly motivated individual or couple without a family history requests cystic fibrosis carrier testing, the current state-of-the-art (as set forth above) should be carefully explained by the physician, either directly or by a genetic counseling center. After this explanation, if the individual still wants to be tested, it is not unreasonable for the physician to comply with this request.

Quality control of all aspects of the laboratory testing, including systematic proficiency testing, is required and should be implemented as soon as possible. Accurate screening and counseling will require reliable test results. It is thus important that national standards for laboratory testing be established, that the laboratories involved in performing cystic fibrosis testing be monitored in some reasonable manner, and that the results of this monitoring be made available to the medical profession and the public.[16]

There should be equal access to testing. We agree with the National Institutes of Health panel and others that routine screening of the general population is premature at this point. However, if successful pilot programs demonstrate that the benefits outweigh the costs and that counseling can be done effectively, the question will be who should be screened? The National Institutes of Health panel stated: "the most appropriate group for population screening is reproductive aged individuals," and primary health providers were defined as "the optimal setting." Society is currently wrestling with the issues of whether cystic fibrosis screening should be covered by public insurance and of what the minimum benefit package should consist. Unless the cost of the test can be reduced from its present $150 to $200, it may be difficult to justify population screening covered by private insurance, even more difficult to justify population screening covered by public insurance, and even more difficult yet to justify screening black Americans. Additional cost and benefit data will be needed to make this assessment.

Ideally cystic fibrosis screening would be performed before pregnancy, at a time when couples still have such options as artificial insemination, adoption, or not having children at all. Some couples might choose to be screened but even when identified as cystic fibrosis carriers elect to take their chances with the knowledge that there is "only" a 25% risk of having an affected child. However, screening adults for heterozygosity is generally useful only if prenatal diagnosis is available. At present, it can be assumed that couples in which both partners are identified to be heterozygotes for cystic fibrosis would usually proceed to prenatal diagnosis with the intent of pregnancy termination if the fetus is found to be affected.

Inevitably, this will become an increasingly difficult choice for some couples. This is not only because many affected children cope with their disease admirably and even live for four decades, but also because with the cloning of the cystic fibrosis gene and the determination of the gene product cystic fibrosis transmembrane conductance regulator, there is new optimism that either somatic gene therapy or medical therapy targeted toward the underlying abnormalities will provide a "cure" or significant amelioration for patients with cystic fibrosis in the foreseeable future.

Before they undergo amniocentesis or chorionic villus sampling, couples who are cystic fibrosis carriers will need knowledgeable counseling by experts in cystic fibrosis who can accurately detail, in unbiased fashion, the probable clinical course of the disease, as well as the medical progress being made in its treatment. At some point it is to be hoped that cystic fibrosis will no longer be a reason to consider pregnancy termination. At present, however, the final decision regarding pregnancy termination must rest with the accurately counseled couple.

The obligations of obstetrician-gynecologists

Screening that is offered as part of more generalized health care services (e.g., through high school, college, or family planning clinics) would encourage preconceptual cystic fibrosis carrier screening. For most couples, however, the first opportunity for carrier screening takes place after a pregnancy has occurred. The primary responsibility for providing cystic fibrosis carrier screening will rest with obstetrician-gynecologists, as does the provision of other types of genetic screening, such as tests recommended because of advanced maternal age or screenings for maternal serum α-fetoprotein, hemoglobinopathies, or Tay-Sachs disease.

One important recommendation of the National Institutes of Health panel was that cystic fibrosis screening "should be offered to all individuals and/or couples with a family history of cystic fibrosis." On the other hand, for many of the reasons already detailed, the group recommended against screening those individuals with a negative family history "under the current circumstances." This recommendation is consistent with recent professional organization statements. The Committee on Obstetrics: Maternal and Fetal Medicine of the American College of Obstetricians and Gynecologists has reviewed and agreed with a policy statement written by the American Society of Human Genetics, which states the following:

First, carrier testing should be offered to couples in which either partner has a close relative affected with [cystic fibrosis]. Second, one or a few federal, foundation, or privately supported pilot programs should be conducted as soon as possible in order to gather more data regarding laboratory, educational and coun-

seling aspects of screening. Third, there is an immediate need for centralized quality control of laboratories conducting these tests. Fourth, it will be appropriate to begin large-scale population screening in the foreseeable future, once the test detects a larger proportion of [cystic fibrosis] carriers and more information is available regarding the issues surrounding the screening process. Until that time it is considered premature to undertake population screening.

Finally . . . it is the position of the American Society of Human Genetics that routine [cystic fibrosis] carrier testing of pregnant women and other individuals is NOT yet the standard of care in medical practice.[17]

Current "standard of care" by obstetrician-gynecologists should include a genetic history and should offer (not require) prenatal diagnostic testing to couples who have had a previous child with cystic fibrosis.[18] The real question is how we decide whether cystic fibrosis screening should be routinely recommended for individuals of reproductive age who have a negative family history. The President's Commission on Bioethics,[14] for example, stated: "Public screening programs should not be implemented until they have first demonstrated their value in well-conducted pilot studies." The National Institutes of Health panel concurred with this recommendation in the following statement:

Pilot programs investigating research questions in the delivery of population screening for CF carriers are urgently needed. These programs should address clearly defined questions including effectiveness of educational materials, level of utilization, laboratory aspects, counseling issues, costs, and beneficial and deleterious effects of screening.

We agree. Good science and solid educational and counseling strategies must be in place before cystic fibrosis screening is routinely offered to those with a negative family history. Unlike maternal serum α-fetoprotein screening, in which a primary impetus for introduction as a routine test was to avoid malpractice suits,[19] cystic fibrosis carrier screening should be deemed "standard of care" only after the appropriate scientific committees (e.g., the Committee on Obstetrics: Maternal and Fetal Medicine of the American College of Obstetricians and Gynecologists) have reviewed all relevant data, including those on educational strategies, and have concluded that offering such screening will probably provide more benefit than harm to individuals and couples. This will help ensure that cystic fibrosis carrier screening will be introduced in a coordinated and effective manner.

Under the influence of aggressive private companies that are marketing cystic fibrosis tests, individual practitioners may "jump the gun" and offer routine cystic fibrosis screening. The medical profession can still be effective in managing the introduction of cystic fibrosis testing and screening into clinical practice. This is important, because ad hoc approaches to genetic screening, such as those used to identify sickle cell anemia, Tay-Sachs disease, maternal serum α-fetoprotein, and now cystic fibrosis screening, are ultimately unsatisfactory.[15] As the human genome initiative continues, tens, if not hundreds of new genetic screening tests may compete for introduction into routine clinical practice. It is past time to begin to develop guidelines for determining how we should judge each such new test, which tests should be routinely offered, and who should pay for each of them. Current procedures in which professional associations such as the American College of Obstetricians and Gynecologists and expert panels at the National Institutes of Health make recommendations do not contemplate or include effective participation by the public in such decisions. Because the public will ultimately be asked to accept or refuse such screening and because the ultimate objective of all such screening is to benefit the public, we recommend that all such groups take steps to involve the public in their deliberations about which screening tests physicians should routinely offer to their patients.

Addendum

Since submission of this manuscript, the cystic fibrosis mutation detection rate has increased to about 85%. As shown in Table II, 72.3% of cystic fibrosis carrier couples could now be identified.

Determinants of perinatal outcome in pregnancy-induced hypertension with absence of umbilical artery end-diastolic frequencies

Fiona M. Fairlie, MD,[a] Michael Moretti, MD,[b] James J. Walker, MD,[a] and Baha M. Sibai, MD[b]

Glasgow, Scotland, and Memphis, Tennessee

Forty-three pregnancies that were complicated by pregnancy-induced hypertension and either absence of umbilical artery end-diastolic frequencies ($n = 32$) or reversal of umbilical artery end-diastolic frequencies ($n = 11$) were reviewed. The incidence of perinatal mortality and morbidity was similar for the two Doppler patterns. Perinatal survival was highly dependent on the gestational age when hypertension first appeared. Presentation at ≥30 weeks' gestation was associated with a perinatal survival rate of 86%. Presentation at <30 weeks' gestation was associated with a perinatal survival rate of 38% ($p < 0.005$). Pregnancy-induced hypertension that presented before 30 weeks was more often associated with a 5-minute Apgar score <7 ($p < 0.005$) and a nonreactive nonstress test ($p < 0.05$) compared with pregnancy-induced hypertension that presented at or beyond 30 weeks. For pregnancies that presented before 30 weeks, the only difference between perinatal survivors ($n = 11$) and perinatal deaths ($n = 18$) was a higher incidence of birth weight at or below the 10th percentile among deaths ($p = 0.02$). (Am J Obstet Gynecol 1991;164:1084-9.)

Key words: Absence of end-diastolic frequencies, Doppler ultrasonography

The absence of end-diastolic frequencies in the umbilical artery Doppler waveform is a normal finding before 18 weeks' gestation.[1] After 20 weeks' gestation, absence of end-diastolic frequencies is not normal and has been shown to be associated with high perinatal mortality and morbidity rates.[2,3] The reported perinatal mortality rate that is associated with this Doppler finding ranges from 17% to 89%.[3-5] Reversal of end-diastolic frequencies is the most severe umbilical artery waveform abnormality.[6] It has been suggested that almost all fetuses with reversal of end-diastolic frequencies are asphyxiated.[7]

The optimum management of pregnancies with absence of end-diastolic frequencies or reversal of end-diastolic frequencies is controversial. Some have recommended immediate delivery in all cases,[4] and others suggest delivery in selected cases according to gestational age and the presence or absence of other risk factors.[7] The small size of studies to date, the inclusion of a variety pregnancy complications, and fetuses with lethal abnormalities have made it difficult to determine the most appropriate method of management of this Doppler pattern.

In this article, we report on our experience of absence of end-diastolic frequencies and reversal of end-diastolic frequencies in pregnancy-induced hypertension. The purpose of our study was to identify factors that correlate with perinatal outcome and may prove useful in determination of the appropriate management of pregnancy-induced hypertension that is complicated by absence of end-diastolic frequencies or reversal of end-diastolic frequencies.

Patients and methods

Two centers participated in this study, the E.H. Crump Hospital and Perinatal Center in Memphis, Tennessee and the Glasgow Royal Maternity Hospital in Scotland. Between January 1, 1986, and July 1, 1989, 43 pregnancies that were complicated by hypertension were found to have absence or reversal of umbilical artery end-diastolic frequencies. Thirty-two pregnancies were complicated by preeclampsia[8] (American Col-

From the Perinatal Research Center, Glasgow Royal Maternity Hospital,[a] and the E.H. Crump Women's Hospital and Perinatal Center, Memphis.[b]

lege of Obstetricians and Gynecologists definition).[8] Eleven pregnancies were complicated by pregnancy-induced hypertension without proteinuria.

In Glasgow, Doppler studies were performed with a Doptek continuous wave system (Doptek, Chichester, England). A 150 Hz high-pass filter was used to eliminate low-frequency signals that are caused by vessel wall movement. In Memphis, Doppler recordings were obtained with an Ultramark 9 (Advanced Technology Laboratories, Inc., Bothell, Wash.) with continuous-wave and pulsed-wave Doppler ultrasonography and a 50 Hz high-pass filter.

Umbilical artery waveforms were recorded from free-floating loops in the midportion of the umbilical cord. A diagnosis of absence of end-diastolic frequencies or reversal of end-diastolic frequencies was accepted when this Doppler pattern was demonstrated at three separate sampling sites. Doppler signals were recorded in the absence of fetal breathing and trunk movements. Uteroplacental flow-velocity waveforms were recorded on the right and left sides with continuous-wave Doppler ultrasonography with the technique described by Schulman et al.[9] A normal uteroplacental pattern was defined by a mean systolic/diastolic ratio of less than 2.7.[9] Since the patients in this study were recruited from two distinct population groups it was considered inappropriate to use normal Doppler data from either Glasgow or Memphis. For this reason the normal range that was published by Schulman et al.[9] was used. In both participating centers, Doppler measurements were concealed from the obstetricians who were responsible for patient management.

All pregnancies that were studied had ultrasonographic studies dated from before 24 weeks' gestation. Amniotic fluid volume was classified as normal, reduced, or oligohydramnios by subjective assessment and measurement of the largest cord-free pocket. Oligohydramnios was defined as the absence of cord-free pocket with a vertical diameter of ≥2 cm. The nonstress test was classified as reactive if there were at least two accelerations of the fetal heart rate of 15 beats/min amplitude and 15 seconds' duration within a 20-minute recording period.[10] If two accelerations were not evident after a 20-minute recording period, the fetus was stimulated by either vibratory or acoustic stimulation.[11] A fetal heart rate pattern that did not become reactive after fetal stimulation was classified as nonreactive. If a nonreactive pattern was associated with spontaneous fetal heart rate decelerations, it was classified as decelerative. When the result of a nonstress test was nonreactive, a biophysical profile was performed with the technique described by Manning et al.[12]

Both centers that participated in this study attempted to prolong pregnancy unless there was evidence of fetal and/or maternal distress.[13-16] Antihypertensive therapy was administered to 38 patients (88% of study group). Maternal indications for delivery included uncontrollable hypertension, eclampsia, thrombocytopenia (platelet count ≤100,000 per cubic millimeter) and the HELLP syndrome (*h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelets) as defined according to Sibai et al.[17] Elevated liver enzymes were not an indication for delivery unless the elevation was accompanied by another complication. The principal fetal indications for delivery were either a nonreactive nonstress test with spontaneous decelerations or ultrasonic evidence of fetal growth retardation with reduced amniotic fluid volume or oligohydramnios. In four cases, the indication for delivery was a biophysical profile score ≤4 of 10 on two occasions that were separated by a period of 6 hours. Since a biophysical profile was only performed on patients with a nonreactive nonstress test (i.e., 20 patients), it was not considered in the analysis of results.

The following perinatal outcome data were collected; birth weight, birth weight percentile for gestation, mode of delivery, 5-minute Apgar score, umbilical venous blood pH, partial pressure of oxygen, and partial pressure of carbon dioxide, and the incidence of intraventricular hemorrhage, necrotizing entercolitis, and seizures. Birth-weight percentile was defined according to the growth charts of Brenner et al.[18] for the Memphis population and according to those of Forbes and Smalls[19] for the Glasgow population. Venous blood gases in the cord were classified as normal or abnormal according to the normal reference ranges of Nicolaides et al.[20] All neonates were followed up until they left the hospital. In this study, perinatal deaths included stillbirths, deaths within the first month of life, and deaths of infants who died before the age of 12 months without leaving the neonatal unit.

Statistical analysis was performed with either the Student *t* test or Fisher's exact test.

Results

There were 23 survivors and 20 perinatal deaths. The perinatal deaths included 8 intrauterine fetal deaths, 11 neonatal deaths, and 1 infant death. The infant death occurred at 149 days of age. Six survivors are currently younger than 12 months old. All six showed normal physical and neurologic development at 9-month follow-up. Four survivors have bronchopulmonary dysplasia.

The incidence of cesarean section for the total study group was 79%. Of the 35 live-born infants, 34 were delivered by cesarean section, and in 32 cases, delivery was before the onset of labor. One patient who presented at or beyond 30 weeks' gestation delivered vaginally.

There were 32 pregnancies with absence of umbilical

artery end-diastolic frequencies and 11 pregnancies with reversal of end-diastolic frequencies. Table I compares perinatal mortality and morbidity for these two Doppler groups. There was no difference in any of the outcome parameters that were studied.

Preliminary data analysis indicated that there was a dramatic improvement in perinatal survival if pregnancy gestation was at or beyond 30 weeks' gestation when hypertension first presented. Since the main purpose of the study was to identify determinants of perinatal outcome in the presence of absence of end-diastolic frequencies or reversal of end-diastolic frequencies, pregnancies in which hypertension presented before 30 weeks' gestation were compared with pregnancies in which hypertension presented at or beyond 30 weeks' gestation. This comparison is shown in Table II. The initial impression of a significantly higher perinatal survival if hypertension presented at or beyond 30 weeks' gestation was confirmed ($p < 0.005$). All intrauterine fetal deaths occurred in pregnancies in which hypertension presented before 30 weeks' gestation. Seven patients were delivered of infants because of maternal indications, and all presented before 30 weeks' gestation ($p \leq 0.05$). These pregnancies resulted in four survivors and three neonatal deaths. Pregnancy losses at or beyond 30 weeks' gestation were confined to two neonatal deaths after deliveries at 30 weeks' gestation. The birth weights of these neonates were 870 gm and 614 gm, and death occurred at 8 days and 3 days after delivery, respectively. Both infants had severe respiratory distress and intraventricular hemorrhage.

In Table II, fetal monitoring test results were the ultimate test results before delivery. In all cases, the interval between the last monitoring test and delivery did not exceed 4 days. In a comparison of pregnancies that presented before 30 weeks' gestation with those that presented at or beyond 30 weeks' gestation, there was no difference in the incidence of reversal of end-diastolic frequencies. A reactive nonstress test was more common at or beyond 30 weeks ($p < 0.05$). There was no difference in the incidence of decelerative nonstress test pattern. Both abnormal amniotic fluid volume (i.e., reduced amniotic fluid volume or oligohydramnios) and birth weight at or below the 10th percentile were significantly more common at or beyond 30 weeks' gestation ($p < 0.05$). There was a higher incidence of 5-minute Apgar scores <7 in pregnancies that presented before 30 weeks' gestation ($p < 0.005$), but no difference in the incidence of neonatal morbidity. Uteroplacental data were obtained for 27 patients (63% of the study group). There was no difference in a comparison of the incidence of abnormal uteroplacental Doppler studies in pregnancy-induced hypertension that presented before 30 weeks with pregnancy-induced hypertension that presented at or beyond 30 weeks.

Only two pregnancies that presented before 30 weeks' gestation delivered at or beyond 30 weeks' gestation. Pregnancies that presented before 30 weeks' gestation and resulted in perinatal survival ($n = 11$) were compared with pregnancies that presented before 30 weeks' gestation and resulted in perinatal death (either neonatal death $n = 10$ or intrauterine fetal death $n = 8$). The same characteristics as shown in Table II were compared. The incidence of birth weight at or below the 10th percentile was significantly less among survivors (5 of 11) as compared with perinatal deaths (16 of 18, $p < 0.05$; Fisher's exact test). No other differences were detected.

Thirty-two infants were delivered by elective cesarean section. Umbilical venous blood for gas analysis was obtained at delivery in 17 cases. The results are shown in Table III. In a comparison of survivors with neonatal deaths, there was no difference in the incidence of acidosis, hypoxemia, or hypercapnia at delivery. Eight survivors and five neonatal deaths showed absence of end-diastolic frequencies, and three survivors and one neonatal death showed reversal of end-diastolic frequencies. Two of the three survivors with reversal of end-diastolic frequencies were acidotic, hypoxemic, and hypercapnic, and one was acidotic and hypercapnic. The neonatal death with reversal of end-diastolic frequencies was acidotic, hypoxemic, and hypercapnic.

Serial Doppler data were obtained for 16 survivors and 12 perinatal deaths. The recorded duration of absence of end-diastolic frequencies ranged from 1 to 10 days for survivors and 1 to 18 days for perinatal deaths. The recorded duration of reversal of end-diastolic fre-

quencies ranged from 1 to 4 days for survivors and 1 to 2 days for deaths. Two pregnancies were followed up for more than 14 days. One resulted in an intrauterine fetal death at 29 weeks. The other was delivered at 29 weeks and neonatal death occurred at 24 days. In five pregnancies, absence of end-diastolic frequencies preceded a change in the nonstress test. The interval between the first recording of absence of end-diastolic frequencies and the change in the nonstress test ranged from 1 to 14 days. In three cases, the nonstress test changed from reactive to decelerative, and in two cases, the change was from nonreactive to decelerative. Four of these infants were delivered by elective cesarean section because of fetal distress and all survived. The fifth member of this group died in utero.

Comment

Most previous reports of absence of end-diastolic frequencies or reversal of end-diastolic frequencies have been limited to fewer than 30 cases and have included a variety of pregnancy complications and fetal abnormalities. Our study is unique by virtue of its size and by its restriction to one specific pregnancy complication with the exclusion of fetal abnormalities.

It has been suggested that reversal of end-diastolic frequencies is a more ominous sign, in terms of perinatal outcome, than absence of end-diastolic frequencies.[6] This was not evident in our study group. The perinatal mortality that was associated with absence of end-diastolic frequencies was 44% as compared with 54% for mortality that was associated with reversal of end-diastolic frequencies. The incidence of perinatal morbidity and gestational age at delivery was also similar for these two groups. In our experience of pregnancy-induced hypertension that was associated with absence of end-diastolic frequencies or reversal of end-diastolic frequencies, gestational age at presentation was a more important determinant of perinatal outcome than was the severity of the umbilical artery Doppler abnormality.

The purpose of our study was to identify characteristics of pregnancies with pregnancy-induced hypertension and absence of end-diastolic frequencies or reversal of end-diastolic frequencies, which correlated with perinatal outcome and may prove helpful in antepartum management. Gestation at presentation of hypertension was a major determinant of perinatal mortality and morbidity (Table II). Presentation before 30 weeks was associated with a significantly lower incidence of survivors and with significantly more intra-

uterine fetal deaths as compared with pregnancy-induced hypertension that occurred at or beyond 30 weeks. Nonstress test reactivity and Apgar scoring are partly dependent on gestational age. However, it is difficult to explain the significantly lower incidences of reactive nonstress tests and Apgar scores ≥7 in pregnancies that presented before 30 weeks on the basis prematurity alone. In addition, maternal complications were more common among pregnancies that presented before 30 weeks' gestation. These differences are in keeping with a more severe disease process if pregnancy-induced hypertension presented before 30 weeks.

Table II shows the incidence of delivery because of fetal indications to be higher after 30 weeks. However, if intrauterine fetal deaths are taken into account, then the incidence of delivery because of fetal indications was the same before 30 weeks as at or beyond 30 weeks. It may be postulated that at gestations before 30 weeks, obstetricians decided that the risk of neonatal morbidity and mortality was too high to justify delivery. Consequently, the asphyxiated fetus died in utero. However, it is not possible to conclude from this study that immediate delivery for pregnancy-induced hypertension that presents before 30 weeks will improve perinatal outcome.

It is unlikely that the method of delivery had a major impact on perinatal outcome since 97% of live-born infants were delivered by cesarean section. For pregnancies that presented before 30 weeks' gestation, infants that died during the perinatal period were more likely to be small for gestational age (below the 10th percentile of birth weight for gestation) compared with survivors. Although placental function is not the only determinant of perinatal survival and birth-weight percentile, it is an important factor. In our study group, the incidence of abnormal uteroplacental Doppler results was high—85% of all pregnancies studied. We found no correlation between the uteroplacental Doppler waveform and perinatal outcome. This finding agrees with the conclusions of Trudinger and Cook[21] who studied uteroplacental Doppler waveforms in severe pregnancy-induced hypertension.

Gas analysis of umbilical cord blood that was obtained at cordocentesis correlates well with samples that were obtained at elective cesarean section.[22] We compared cord venous blood gas analysis after elective cesarean section for survivors and neonatal deaths and found no difference in the incidence of acidosis, hypoxemia, or hypercapnia. It has been suggested that virtually all fetuses with umbilical artery reversal of end-diastolic frequencies are asphyxiated and that cordocentesis may be of value in assessment of the well-being of the previable fetus with absence of end-diastolic frequencies.[7] We found a high incidence of abnormal gases in association with both absence of end-diastolic frequencies and reversal of end-diastolic frequencies, regardless of perinatal outcome. This would suggest that blood gas analysis by cordocentesis may benefit only a very small proportion of fetuses with absence of end-diastolic frequencies or reversal of end-diastolic frequencies, that is, those with normal blood gases. In a study of umbilical blood samples that were obtained at cordocentesis from fetuses that were small for gestational age, Nicolaides et al.[20] concluded that umbilical venous hypoxemia or hyperlactacidemia were good determinants of uteroplacental insufficiency. It is interesting that Table III shows a trend (nonsignificant) toward less hypoxemia among survivors as compared with neonatal deaths.

Johnstone et al.[3] described the outcome of 24 pregnancies with absence of umbilical artery end-diastolic frequencies. Twenty were delivered by cesarean section, and 22 were below the 5th percentile. There were four deaths—a much lower perinatal mortality rate than that reported in other studies of absence of end-diastolic frequencies. Four pregnancies continued for 3 to 6 weeks after the finding of absence of end-diastolic frequencies. Only one of these four had signs of fetal distress, and only two were delivered vaginally. The duration of absence of end-diastolic frequencies in these four pregnancies is interesting. In our study, the duration of absence of end-diastolic frequencies ranged from 1 to 18 days in the two pregnancies that were followed up for more than 2 weeks, and both resulted in perinatal death. The exact duration of absence of end-diastolic frequencies or reversal of end-diastolic frequencies is unknown unless daily Doppler examinations are performed. However, the impression from our study and previous studies is that fetuses vary in their ability to tolerate the vascular pathologic conditions that are responsible for absence of end-diastolic frequencies.[3, 23] Our experience confirms the observation, which was reported by others,[3, 23] that absence of end-diastolic frequencies may precede a change in the nonstress test by a variable time interval.

We would agree with other authors that absence or reversal of umbilical artery end-diastolic frequencies is associated with a high risk of adverse perinatal outcome but is not an indication for immediate delivery. In our specific study group of pregnancies that were complicated by pregnancy-induced hypertension, perinatal mortality and morbidity were almost entirely confined to hypertension that presented before 30 weeks' gestation. For pregnancies that presented beyond 30 weeks' gestation, delivery that was based on traditional tests of fetal monitoring (i.e., nonstress tests and ultrasonic assessment of fetal growth and amniotic fluid volume) was associated with 86% perinatal survival. It may be postulated that for pregnancies that present before 30 weeks' gestation, perinatal outcome could be im-

proved by prolonging gestation. However, this is only possible if the fetus is healthy and if maternal condition is stable.

Intrauterine transfusion treatment of nonimmune hydrops fetalis secondary to human parvovirus B19 infection

Vicken Sahakian, MD,[a] Carl P. Weiner, MD,[a] Stanley J. Naides, MD,[b] Roger A. Williamson, MD,[a] and Laura L. Scharosch, AB[b]

Iowa City, Iowa

Congenital human parvovirus B19 infection presented in this case as nonimmune hydrops fetalis that resulted from aplastic anemia at 20 weeks' gestation. Intravascular transfusion therapy led to resolution of the hydrops and a term delivery of an appropriately grown neonate. (AM J OBSTET GYNECOL 1991;164:1090-1.)

Key words: Nonimmune hydrops fetalis, parvovirus, cordocentesis

Human parvovirus B19 was first identified in 1975 and has subsequently been shown to be the cause of several diseases, including aplastic crisis in patients with chronic hemolytic anemia, erythema infectiosum, a chronic rheumatoid-like arthritis, and chronic bone marrow suppression.[1] The most common clinical presentation of parvovirus in an infected fetus with symptoms is nonimmune hydrops. The hydrops can result either from aplastic anemia with high-output cardiac failure or from myocarditis. Intrauterine fetal therapy with digoxin for the latter condition has been attempted but has been only partially successful.[2] Theoretically, treatment of an aplastic crisis should be straightforward. Recently, Peters and Nicolaides[3] reported the reversal of B19 hydrops in two fetuses after antenatal transfusion. We wish to report a third case, which supplies additional biochemical and biophysical parameters that shed further light on the involved pathophysiology.

Case report

A 23-year-old primigravid woman was referred to the University of Iowa Fetal Diagnosis and Treatment Unit in September 1989 at 21 weeks' gestation after fetal hydrops was found during a routine ultrasonographic examination approximately 1 week earlier. The patient had recently begun work at a children's day-care center. She denied signs or symptoms that would be compatible with a viral illness during the pregnancy.

A level II ultrasonographic examination revealed a fetus with biometric parameters that were consistent with 21 weeks' gestation. Anhydramnios and frank anasarca that were characterized by subcutaneous edema, fetal ascites, and cardiomegaly with a pericardial effusion were detected. In addition, the lateral cerebral ventricles were modestly dilated.

A cordocentesis was performed (Table I). The pancytopenia was consistent with a viral infection as was the total level of immunoglobulin M (IgM) of 46 mg/dl (upper limits of normal, 10 mg/dl). The umbilical venous pressure was elevated and consistent with congestive heart failure. An intravascular transfusion was performed through the umbilical vein on an emergent basis and the hematocrit partially corrected to 22%. The transfusion was repeated 48 hours later, at which time the final hematocrit was 39%. The umbilical venous pressure had normalized by the time of the second transfusion.

A maternal B19 serologic test was performed with an antibody-capture enzyme-linked immunosorbent assay as previously described.[1] Both IgM and immunoglobulin G (IgG) anti-B19 antibodies were positive in maternal serum on Sept. 6, 1989. Electron microscopic examination of fetal blood and nonheparinized fetal ascites by negative staining revealed viral particles that were morphologically consistent with B19 as previously described.[2] Polymerase chain reaction amplification of B19 deoxyribonucleic acid was performed with B19-specific primers, and Southern analysis was performed with a B19-specific probe as previously described.[1] B19 deoxyribonucleic acid was detected in fetal serum and ascites on Sept. 6, 1989, and in fetal serum 2 weeks later, on Sept. 19, 1989. There was no evidence of viremia in maternal serum when it was tested on Sept. 6, 1989, and on Sept. 20, 1989.

Two weeks after the transfusion therapy, the fetal hematocrit was stable and the reticulocyte index had risen to 4.9% (Table I). There was clear improvement in the liver function studies. Significantly, the total level of IgM had already declined to 15 mg/dl.

The fetus was closely monitored. All ultrasono-

graphic abnormalities resolved over the next 4 weeks. Delivery occurred at term in the referring hospital. Cord serum that was obtained at delivery was negative for anti-B19 IgM but positive for IgG anti-B19 antibodies. At the time of delivery, fetal viremia was no longer detected. The 7-pound 8-ounce male infant was in good condition and was discharged with his mother. At 1 year of age his development remains normal.

Comment

A causal relationship between B19 infection and hydrops fetalis with subsequent fetal death has been documented.[2] The antenatal diagnosis and palliative treatment of parvovirus B19 nonimmune hydrops fetalis in association with myocarditis was first reported in 1989.[2] Although the hydrops resolved with direct fetal digitalization, that fetus died of overwhelming myocarditis. This case, in which the hydrops was associated with severe anemia, appears to be the third fully documented case of antenatal diagnosis with treatment by intrauterine transfusion, complete resolution of hydrops, and a viable outcome. A fourth case has been reported in preliminary form, but documentation of fetal infection was limited to the demonstration of maternal anti-B19 IgM antibodies and B19-like particles in fetal serum.[4]

Early in gestation, the fetus is particularly vulnerable because of a shortened erythrocyte life span and hyperplastic erythropoiesis. The pathogenesis of the hydrops frequently appears to be secondary to the cytopathic infection of red blood cell precursors with arrest of red blood cell production, resultant severe anemia, and subsequent congestive heart failure. The severe anemia that was present in our case and associated with a low reticulocytic index and a normal bilirubin level suggests a similar pathogenesis as opposed to hemolysis. The very low white blood cell and platelet counts probably reflect suppression of the myeloid and thrombopoietic cell lines in addition to the erythropoietic ones. The elevated liver function tests are consistent with hepatic dysfunction, including hepatitis (unpublished norms from the Iowa Fetal Diagnosis and Treatment Unit).

Two weeks after transfusion, the hematocrit was stable and the reticulocyte count doubled. This remarkable recovery offers hope that if the fetus survives the acute infectious episode, survival is possible. In one reported case the hydropic fetus had begun to mount a reticulocytic response when treated and may have recovered without therapy.[3]

In the case presented here, the elevated umbilical venous pressure is consistent with high-output cardiac failure. Its correction with partial transfusion supports hypoxic myocardial dysfunction as at least part of the mechanism. The marked decline of the total IgM antibodies within 2 weeks suggests that the fetal immune system may be too immature to sustain anti-B19 IgM antibody production when the antigenic stimulation occurs before 20 weeks' gestation. This decline further demonstrates that a search for congenital infection should not rely on total IgM measurements.

Table I. Intrauterine transfusion therapy

Laboratory test	*Before transfusion*	*2 wk after transfusion*	*Normal**
Hematocrit (%)	5.8	39.8	30.8-38.4†
White blood cell count (No./mm³)	0.4	2.7	3.11 ± 0.7†
Platelets (No./mm³)	31,000	113,000	255,000 ± 51,000
Reticulocyte count (%)	2.3	4.7	12.2 ± 3.6†
Lactate dehydrogenase (IU/L)	925	375	202 ± 30†
Aspartate aminotransferase (IU/L)	52	12	13 ± 3†
Total bilirubin	1.1	2.2	1.4 ± 0.2†

†For gestational age.

The complete resolution of hydrops after fetal transfusion also suggests that fetal B19 infection is a self-limited infection that will eventually be followed by recovery if the fetus survives the acute initial insult. This case report of a B19-infected fetus suggests that intrauterine transfusion may be used as a last resort for the treatment of such severely affected hydropic fetuses.

We acknowledge the referral of this patient by Wayne Conover, MD, and pediatric follow-up by Norma Hirsch, MD, Methodist Hospital, Des Moines, Iowa.

Attitudes on the ethics of abortion, sex selection, and selective pregnancy termination among health care professionals, ethicists, and clergy likely to encounter such situations

Mark I. Evans, MD,[a] Arie Drugan, MD,[b] Sidney F. Bottoms, MD,[a] Lawrence D. Platt, MD[c] Charles A. Rodeck, MD,[d] Manfred Hansmann, MD,[e] and John C. Fletcher, PhD[f]

Detroit, Michigan, Haifa, Israel, Los Angeles, California, London, England, Bonn, Federal Republic of Germany, and Charlottesville, Virginia

The ethical attitudes of health care providers toward abortion, sex selection, and selective termination of normal and anomalous fetuses in singleton or multiple pregnancies were evaluated by questionnaires distributed to members of the American Society of Human Genetics, the International Fetal Medicine and Surgery Society, the Society of Perinatal Obstetricians, ethicists, and clergy. Demographic characteristics of respondents exhibited a preponderance of men (76%), age >40 (68%), and of United States residents (82%). Seventy-nine percent of respondents were in the medical profession. Approximately half of the respondents were Protestant, the rest being evenly distributed among Catholic, Jewish, and other religions. Acceptance of abortion for social indication varied by religion and gestational age but not by religious conviction, age, country, or gender of respondent. First-trimester abortion of a normal singleton pregnancy was considered more acceptable than selective termination of normal fetuses in multifetal gestations. Sex selection was considered unethical by most respondents. Selective termination was deemed ethically appropriate in quadruplets or multifetal gestations of more than five fetuses and in multiple pregnancies bearing one anomalous fetus. In the latter situation, acceptance increased with the severity of fetal anomalies and decreased from the first to the third trimester. The medical specialty of respondents was the only independent factor strongly associated with acceptance of selective termination by trimester, indication, and number of fetuses. Acceptance of selective termination among health care professionals appears to reflect not only perceptions of procedure-related risks and benefits in the index pregnancy but also individual training and religious beliefs. (AM J OBSTET GYNECOL 1991;164:1092-9.)

Key words: Abortion, sex selection, selective termination, ethics

The recent debate after the United States Supreme Court decision on *Webster vs Reproductive Health Services* has reopened legal questions concerning a woman's ability to obtain an abortion. In the next several years, state laws may diverge dramatically from the protection that *Roe vs Wade* gave from interference by states with a woman's choice.

The ethics of controversial topics such as abortion per se, sex selection, and selective termination must be studied and shaped independently from the legal and political processes. We undertook to survey those professionals likely to encounter pregnant patients who might be candidates for difficult choices such as whether to have an abortion for fetal abnormalities or a selective termination for either an abnormality or a multifetal pregnancy. We then compared their views on the ethical appropriateness of such procedures against their baseline view of abortion for nonobstetric-nonmedical indications ("social abortion") and abortion for sex selection. The study questions were: Do these professionals approve of abortion or termination of one or more fetuses under any circumstances? What do their views suggest about the actual shape of moral reasoning in practice?

These data were all obtained before *Webster* and therefore may be used in the coming years as a benchmark for change in ethical views as changes in the law may force changes in medical practice.

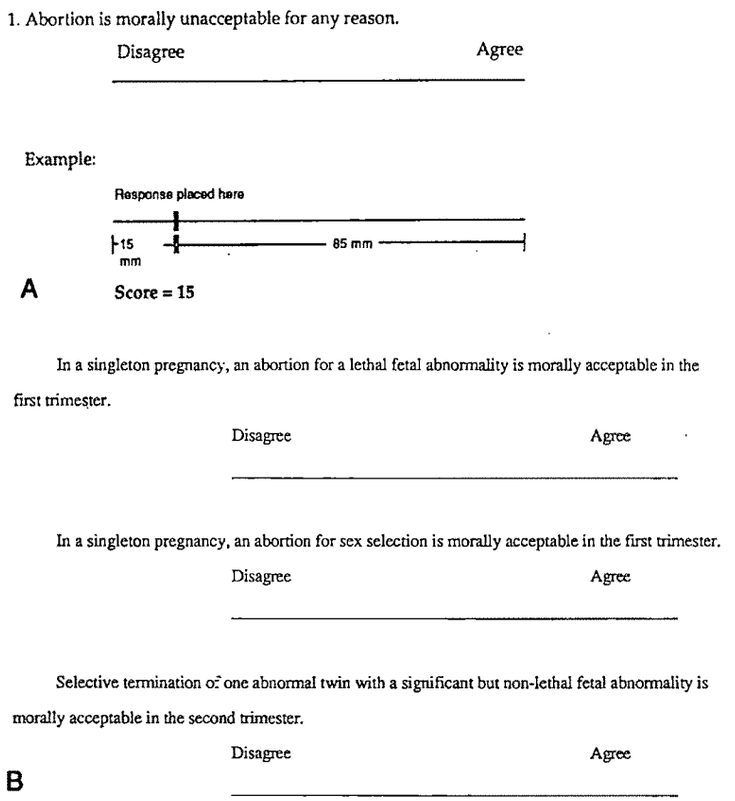

Fig. 1. Example of statements **(A)** and method of response **(B).**

alies, sex selection, and selective termination in twins and higher-order multifetal pregnancies were circulated to members of the American Society of Human Genetics (ASHG), the International Fetal Medicine and Surgery Society (IFMSS), the Society of Perinatal Obstetricians (SPO), and ethicists and clergy with known involvement in biomedical issues. Questions were then stratified by the trimester of pregnancy.

We assumed that demographics may influence the response to specific statements. Independent variables used therefore were age (<40, 40 to 49, or ≥50 years), specialty (maternal-fetal medicine, medical [not maternal-fetal medicine], genetics, and nonmedical professionals), country (United States vs others), gender, religion (Protestant, Jewish, Catholic, and others), and religious conviction (the degree that the responder considered himself or herself religious).

Respondents were asked to note degrees of agreement with statements by marks on a 100 mm line, with complete disagreement scored as 0 and complete agreement scored as 100. Scores were determined with a millimeter rule as the distance of the mark from the zero score (Fig. 1, *A*). A few example questions are also shown (Fig. 1, *B*).

To minimize the effects of extreme values ("outliers"), scores were transformed to a nominal scale of 0 to 3; 0 is complete disagreement and 3 is complete agreement with the statements. Multivariate analyses of variance for repeated measures (software, BMDP statistical package, Santa Monica, Calif.) were used to analyze scores. Trimester and number of fetuses were repeated-measures adjusted as within-subject factors. Characteristics of the respondents were between-subject factors and selection on the basis of a priori interest and data reduction with the use of stepwise log-linear analysis. To minimize the effect of multiple comparisons, $p < 0.001$ was considered significant.

Results

The demographic characteristics of the 737 questionnaire respondents' analyzed are shown in Table I. Respondents were predominantly men, over age 40, and therefore would not personally face the dilemma of carrying a multiple pregnancy.

The first statement posed the moral acceptability of social abortion. Most of the respondents (74.1%) strongly disagreed with a statement that abortion in the first trimester is morally unacceptable. The only variable related to this response was religion ($p < 0.001$); first-trimester abortion was more accepted among Jewish respondents than among Moslems or Protestants (in this order) and least accepted among Catholics (Fig.

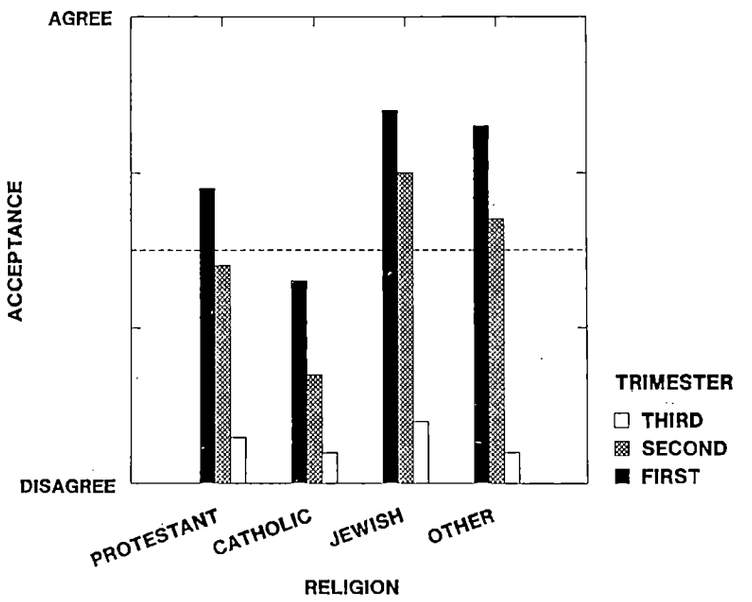

Fig. 2. Acceptance of social abortion, by religion, in first, second, and third trimesters.

Table I. Demographic characteristics of respondents

Characteristic	%
Age (N = 723)	
<40 yr	39
40-49 yr	33
>50 yr	27
Specialty (N = 734)

Other	18
Gender (N = 731)	
Male	76
Female	24

2). In contrast, sex selection of singleton pregnancies in the first, second, or third trimester was found unacceptable by most of the respondents; (67.2%, 74.6%, and 92.5%, respectively). Differences could not be documented by group, age, religion, sex (Fig. 3), specialty, or country of origin. The association with religious conviction was, however, marginally significant (p = 0.0012).

We then questioned the acceptability of selective termination of one or more presumably "normal" fetuses in multifetal gestation. Acceptance of selective termination in this situation increased with the number of fetuses (from two to four) and decreased with advancing gestational age (Fig. 4). Social terminations of singleton pregnancies were perceived as being more acceptable than selective termination for social reasons in twins, triplets, or quadruplets. Agreement with a woman's right to interrupt a normal pregnancy for social reasons and the relative risks of selective termination to remaining fetuses (as compared to risk of multiple gestation) may explain these findings.

Analyses of the factors associated with these results show that the group and specialty of respondents strongly influenced acceptance of selective termination in association with the number of fetuses and trimester ($p < 0.0001$). Acceptance was highest among geneticists and lowest among non-medical ethicists and clergy (Fig. 5). The effects of religion and religious conviction were documented only in relation to trimester, not to number of fetuses. Selective termination for quadruplets was more acceptable among professionals in maternal-fetal medicine than among other groups. The highest acceptance of selective termination was among Jewish respondents; the lowest was among Catholics. A weak association with gestational age was also documented for country and age, whereas the association between these factors and number of fetuses was not significant. The gender of respondent did not influence acceptability of selective termination as evaluated by trimester or by number of fetuses (Table II).

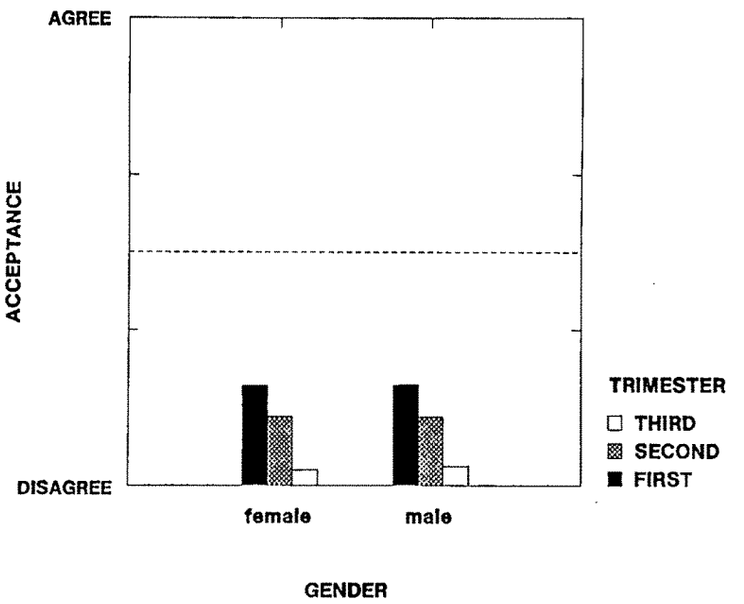

Fig. 3. Acceptance of sex selection, by gender of respondent, in first, second, and third trimesters.

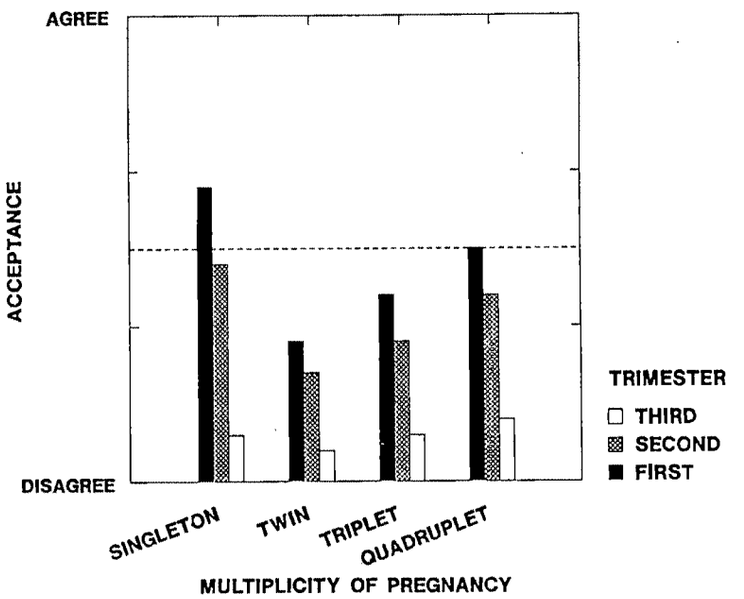

Fig. 4. Acceptance of singleton abortion and selective termination, according to fetal number, in first, second, and third trimesters.

The effects of the indication for termination (social, significant nonlethal anomaly, and lethal anomaly) in twins and singletons also were evaluated. The acceptability of abortion in singletons increased with the severity of anomalies involved and decreased with advancing gestation. The same trend was observed in twins, although the acceptability of selective termination of the affected twin in the second and third trimesters was lower than for singletons. Overall, acceptance of selective termination was strongly associated with the trimester of pregnancy, indication for selective termination, and fetal number (whether it be a singleton or twin gestation).

Specialty was the only independent variable affecting acceptance of selective termination in relation to indication, trimester, and number of fetuses (Table III).

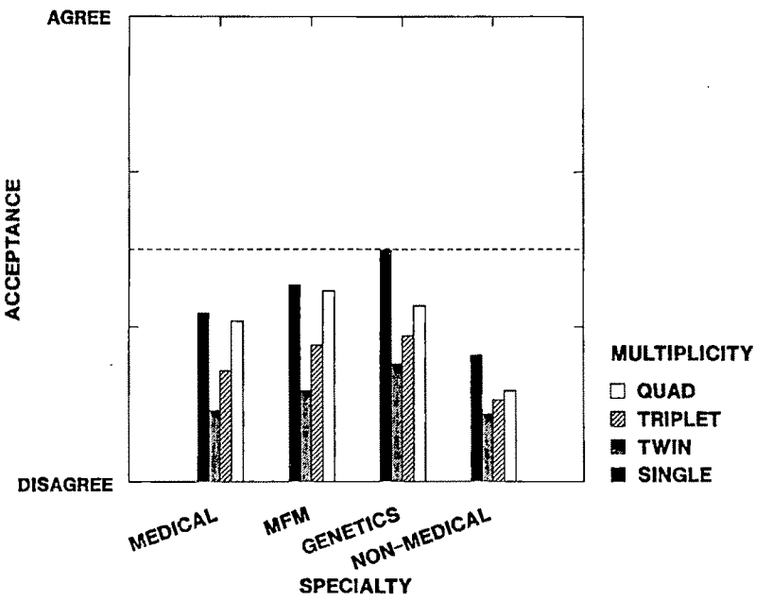

Fig. 5. Acceptance of selective termination according to fetal number and specialty of respondent.

The highest acceptance was among geneticists; the lowest was among nonmedical professionals. A significant difference, according to indication, was also found between United States and non–United States respondents. Acceptability of social terminations was higher in United States respondents whereas acceptability of termination for anomalies was higher for non–United States respondents. The trimester or number of fetuses did not affect this response. Likewise, gender did not influence acceptability of selective termination by indication, trimester, number of fetuses, or any of the interactions within.

Most respondents considered that in multiple pregnancy with two fetuses there is a 95% chance of survival without significant morbidity, and in triplets there is a 90% chance. A 50% chance of intact survival was considered by most as the chance in quadruplets. Most respondents considered that quintuplets have less than a 5% chance of survival with acceptable morbidity for all fetuses. No relationship could be documented between these responses and age, gender, group, specialty, religion, religious conviction, or country.

Quadruplets were elected as the optimal number of fetuses to offer selective termination in the first or second trimester (67.4% and 62.6% of respondents, respectively). The optimal number of remaining fetuses after the procedure was two (67.8%). No interactions were evident between these choices and the independent variables. The minimal number and maximal number of fetuses to be left in utero after selective termination were 2 and 3, respectively. These choices were identical whether the selective termination was performed in the first or second trimester of pregnancy.

The question of safety and the need for centralization of services for selective termination was also addressed by respondents. Only 6.3% of respondents strongly disagreed with the statement that selective termination is a safe procedure in the first trimester, whereas 36.5% of respondents already strongly believed in the safety of this procedure. However, second-trimester procedures were considered less safe. Respondents who completely disagreed and completely agreed with the safety of second-trimester selective termination were 12.1%, and 17% respectively. No relationship could be documented between these responses and age, sex, country, specialty, religion, or religious conviction. More than half of the respondents (52.2%) strongly agreed that selective termination should be performed in a small number of centers with considerable experience in this technique. Again, none of the independent variables was significantly related to this response.

Comment

Our data show the following:

1. Acceptability of abortion in singleton pregnancies increases with the severity of anomalies and decreases with advancing gestation. Acceptability of selective termination of one abnormal twin follows the same general rules but is lower than for singletons in all categories. This may be explained by considerations of risk conferred by the procedure to the normal remaining twin.

2. Acceptability of abortion according to trimester

(but not to number of fetuses and indication) was also determined by religion. A weaker association with the degree of religious conviction was also found. This may indicate that the point in pregnancy when fetal rights become compelling may differ by religion—from conception through the point that a premature fetus is believed to have a reasonable chance of viability, about 24 gestational weeks at present. Acceptance of selective termination in the third trimester, when viability is established, was uniformly low.

3. Specialty was the only independent variable strongly associated with acceptability of termination according to trimester, indication, and number of fetuses. The variation may indicate that acceptance of selective termination may be based on more day-to-day exposure to neonatal problems seen by physicians who specialize in birth defects. However, this conclusion has to be taken with extreme caution. There are many potential confounders to this point, including the underlying assumptions and biases of physicians as to why they went into their respective specialties.

4. Sex selection is not widely accepted among health professionals, ethicists, and clergy. A majority considered that sex selection was not an ethically acceptable reason for offering prenatal diagnosis in otherwise uncomplicated situations. There was relative agreement about the unacceptability of sex selection among all specialties, religions, sex, age, or country of the respondents.

5. Respondents accept selective termination as an ethical procedure in cases of multiple gestation (four or more fetuses) or in cases of fetuses affected by serious anomalies. The acceptance of a woman's prerogative in reproductive decisions and the possible risk to remaining fetuses from the selective termination procedure cause higher acceptance of abortion in singleton pregnancies than of reduction of fetal number. High-risk pregnancy specialists were more concerned about the risks of a multifetal pregnancy having poor outcome than were nonmedical personnel.

6. Age, gender, and country or origin did not significantly influence acceptability of selective termination. However, the higher acceptance of social abortion in the United States as opposed to higher acceptance for severe or lethal fetal anomalies by non–United States respondents may indicate a different set of values in these subgroups.

Thus it seems that, although decisions may be influenced by the training or religious beliefs of some, most health care professionals in this study view selective termination as an ethically acceptable procedure, provided that the benefits that can be expected to outweigh the risks. Both the benefits and risks associated with selective termination are, however, still poorly defined at present. The former can be learned by comparing

Gender	NS	NS	NS

the number of infants born without the risk of prematurity after selective termination with the outcome in several published series of multifetal gestations.[1-6] Increased risks for preeclampsia, postpartum hemorrhage, thromboembolic phenomena, and premature delivery are also reported for mothers with multifetal conceptions.[7] Prolonged bed rest and hospitalization have significant psychological, social, and economic implications. Despite treatment, 15% to 28.6% combined perinatal and infant mortality has been reported with triplets, 38.4% with quadruplets, and 70% with sextuplets.[5, 6] With birth weights <1000 gm the perinatal mortality is 50%, and more than 20% of survivors will suffer moderate to severe handicaps.[8] Thus only about 30% of infants from multifetal pregnancies weighing <1000 gm born in level III hospitals will be considered intact survivors.

The clinical experience and ethical considerations in selective termination procedures have been the subject of several recent reports.[9-12] The presumed benefit of this procedure is to enhance the chances of survival and decrease morbidity among the remaining fetuses. Whether this goal is achieved by selective termination is not clear at present as the world's experience is still only a few hundred cases. The risks could be minimized by limiting the procedure to be performed in only a few centers by individuals with extensive experience in ultrasonographically guided techniques. However, even in experienced hands, the pregnancy loss rate after the procedure is reported to be in the range of

20% to 30%.[12, 13] It is imperative that centers that do perform selective termination share their experiences openly.

The desperate situation imposed by the diagnosis of multifetal pregnancy in patients treated for infertility or severe anomalies incompatible with meaningful life in one twin may cause patients to volunteer for experimental, innovative therapy and sign the consent form without experiencing the true meaning of "informed" consent. It is important to counsel patients on the yet unknown risks and uncertain outcomes of selective termination. It is most importantly that efforts should be extended to minimize the need for this procedure by careful monitoring of ovulation induction and by limiting the number of embryos or gametes transferred in in vitro fertilization or in gamete intrafallopian transfer. However, even with these precautions, some multifetal pregnancies will still occur. Moreover, severe anomalies affecting only one fetus in multifetal gestations will continue to happen occasionally. The choice in these cases seems to be between interruption of the entire pregnancy or the abortion of some fetuses so that others may survive with minimal morbidity. We believe that choosing selective termination is a morally acceptable, albeit experimental procedure. According to our data, this belief is shared by many other health care professionals and by some religious leaders, especially if selective termination is offered in the first trimester.

The data about sex selection, as compared with other indications for abortion, reveal much about the moral views of the respondents. Also, if the views of the respondents are similar to the moral views in society as a whole, these data prompt points of reference in the discussion of public policy on abortion in the post-*Webster* debates. After *Webster*, new debates will occur in each state about the best public policy on abortion and whether it should be restricted or unrestricted.

Our views

Abortions done to protect the woman's life are morally acceptable in virtually every ethical tradition. Abortions done to protect a woman's health or respect her consent to pregnancy are the next consideration. Furthermore, many ethical traditions, and the moral views of the respondents to this study, support the moral justification for abortion of a fetus diagnosed with a severe genetic disorder.

Even in the third trimester, in addition to the indication protection of the life and health of the mother, some have argued that pregnancies can be ethically (and usually legally) ended when there is diagnostic evidence of the following: (1) a condition that is incompatible with life after delivery, (2) the death of the infant is imminent, (3) attempts at treatment would be inhumane, and (4) the only option open would be "comfort care."[14, 15]

A counter argument, however, is that not all reasons to become pregnant, to have an abortion, or to alter the number of fetuses in a pregnancy are morally acceptable. To the extent possible, public policy ought to consider both sides of the situation in abortion or selective termination choices.

The views of our respondents are a good index of the ethical "limits" that should be placed on practitioners in assisting with abortions or selective terminations. Our respondents agreed strongly that abortion for sex selection was morally objectionable, although not all respondents made this judgment about the procedure in the first trimester. We believe but cannot extrapolate from the data that there is a distinction between what is unethical and what should be illegal. Abortion for gender selection violates equality in a radical way. Also, gender is not a disease, and to abort for gender is a precedent for eugenics. *Eugenics* means a deliberate attempt to alter characteristics (or avoid them) that have little or nothing to do with disease. If the eugenics of genetic manipulation is to be avoided in the future, when the human genome is mapped, every precedent for eugenics in this generation should be prevented. Ideally, when there is no problem or a small problem, there is not a need for a law. In fact there have been a few preliminary attempts at the state level (e.g., Pennsylvania, California) to outlaw sex selection, for abortion in toto (Louisiana), but we believe such attempts are hopelessly intertwined with politics and do not encourage good medical care, let alone have the capability to be enforced. No one knows the actual incidence of abortion for sex selection in the United States. Some studies show some openness to this idea, as does this study. Openness does not mean that it actually occurs in practice, although a few cases certainly do in fact occur each year.

Another unethical possibility, but a remove one, is to begin a pregnancy with the prior intent of: (1) abortion to donate fetal tissue for therapy to another, (2) selling fetal tissue after abortion to another, or (3) abortion of the fetus if it is not a compatible bone marrow or organ donor for another. Since it is already against Federal law to *sell* fetal tissue and a National Institutes of Health commission has recommended that decisions to direct donations of fetal tissue before abortion be prohibited,[16] it is likely that state laws will incorporate provisions 1 and 2. Provision 3 is likely to be so rare as not to present a public policy problem. However, we recommend that practitioners not cooperate with requests for prenatal diagnosis and/or abortion related to intentions to define the fetus in advance as a source of organ, marrow, or tissue donation for others. This intent violates the personhood of the future individual, in the sense that he or she would be viewed primarily as a means to an end for another person.

Selective termination in pregnancy (of an affected twin or in cases of multifetal pregnancies) is not "abor-

tion." Abortion literally means the emptying of the human uterus. However, if new abortion laws are to be passed, it is likely that these interventions in pregnancy will become subjects of debate. Participants in the debate from the scientific community are urged to familiarize themselves with the facts of these procedures. The views of our respondents reflect that they believe it to be moral to attempt selective termination of a genetically affected twin and in a multifetal pregnancy that follows infertility treatments. However, they object on moral grounds to selective termination of a normal twin for social or economic reasons. The risks of delivery of normal twins do not, in their view, include dangers or complications sufficient to justify the risks of intervention to eliminate one twin. The entire pregnancy could be lost. Also, there are considerations of the loss of general respect for human life that surround unrestricted selective termination of one twin.

If a public policy on abortion and procedures for selective termination in pregnancies is to be debated, the views of the respondents to this study probably have wide support in the society for a moral position that approves some abortions and procedures and rejects others. A sound abortion law must protect the choices of women to terminate pregnancies to which they did not consent or plan (rape, incest, unplanned pregnancies), those that threaten their lives or health, and those that they desire to terminate after diagnosis of a genetic or chromosomal disorder. The legal "cutoff" periods for these choices must be carefully thought through, in terms of what is known about fetal neural development and the timing of midtrimester procedures for genetic diagnosis.

A public policy could include prohibitions against abortions that are sought only for sex choice and abortions to benefit others, either by sale of tissue for use or by donation. However, public policy should protect the rights of parents (with the expert help of physicians) to make difficult choices in difficult situations.

The significance of amniotic fluid volume during intrapartum fetal acoustic stimulation

Albert P. Sarno, Jr., MD, Major, MC, USA
Los Angeles, California, and Honolulu, Hawaii

The relationship of intrapartum fluid volume to the fetal response to acoustic stimulation was investigated in 112 patients who were in the latent phase of labor. Amniotic fluid volume appears to play an insignificant role in the genesis of fetal heart rate decelerations that occur after fetal acoustic stimulation, regardless of the amount of amniotic fluid present. (Am J Obstet Gynecol 1991;164:1100-1.)

Key words: Amniotic fluid volume, fetal heart rate, fetal acoustic stimulation

The fetal response to externally applied sound stimuli has generated a great deal of clinical research interest recently, although many questions remain to be answered.

Fetal heart rate (FHR) decelerations have been noted to follow a reactive fetal response in 20% to 25% of patients.[1] The cause of this pattern is uncertain but is thought to be due to transient cord compression as a result of the fetal startle response. Recently, Menashe and Sherer[2] have suggested that fetal acoustic stimulation may be contraindicated in cases of oligohydramnios because of an increased risk for cord compression that would lead to prolonged bradycardia. However, data that describe the significance of amniotic fluid volume during fetal acoustic stimulation have not yet been reported.

This study examines the effect of amniotic fluid volume on the fetal response to acoustic stimulation in patients who are in the latent phase of labor.

Patients and methods

The study population consisted of 112 patients who presented in the latent phase of labor to the labor and delivery floor of Women's Hospital at the Los Angeles County/University of Southern California Medical Center or Tripler Army Medical Center in Honolulu, Hawaii. Inclusion criteria were: (1) term gestation ≥36 completed weeks, (2) singleton pregnancy, (3) vertex presentation, and (4) latent phase of labor (≤4 cm dilatation).

Amniotic fluid volume was assessed with a semiquantiative technique, the amniotic fluid index.[3]

Electronic fetal monitoring was instituted and was followed by performance of fetal acoustic stimulation with a 3-second sound pulse with a fetal acoustic stimulator (model 146, Corometrics Medical Systems, Inc., Wallingford, Conn.), sound level 82 dB at 1 m in air. If no acceleration of the FHR was noted within 1 minute, an additional pulse was administered to a maximum of three pulses, each 1 minute apart. A reactive response was defined as one or more accelerations of the FHR that were 15 beats/min from baseline and persisted for 15 seconds. An FHR deceleration was defined as a drop in FHR of at least 15 beats/min that persisted for 15 seconds or more within 1 minute of sound stimulation. A nonreactive response was defined as failure to elicit a qualifying acceleration after any of three separate stimuli and for 10 minutes after the last stimulus. Care was taken to avoid performance of acoustic stimulation during or immediately after a uterine contraction to avoid periods of transient fetal hypoxia and to standardize the technique.

Data were collected and analyzed by χ^2 analysis or Fisher's exact test, with statistical significance at $p < 0.05$.

Results

Fig. 1 shows the incidence of various FHR responses in relation to differing amounts of amniotic fluid. Twenty-nine patients (25.8%) were found to have oligohydramnios (amniotic fluid index ≤ 5.0 cm), 30 patients (26.8%) had borderline fluid volume (amniotic fluid index 5.1 to 8.0 cm), and 53 patients (47.3%) had normal fluid volume (amniotic fluid index > 8.0 cm). The range of amniotic fluid index values was from 0.0 cm to 27.5 cm. There was no significant difference in the incidence of FHR decelerations after a sound stim-

ulus in any subgroup for which amniotic fluid volume was determined. In the presence of oligohydramnios, however, significantly more patients exhibited nonreactive responses when compared with patients who had normal fluid volumes (10.3% vs 0.0%, $p = 0.04$).

Comment

Recently, Menashe and Sherer[2] recommended caution in the use of sound stimulation in cases of oligohydramnios because of the anecdotal experience that variable deceleration of the FHR was more common in this setting.

Therefore before acoustic stimulation is widely applied, the concern that is raised in this anecdotal report regarding oligohydramnios must be addressed.

This study addresses the role of amniotic fluid volume during acoustic stimulation. The findings suggest that amniotic fluid volume appears to play an insignificant role in the genesis of FHR decelerations that occur after fetal acoustic stimulation. Regardless of amniotic fluid volume, approximately 25% of patients exhibited variable decelerations. The vigorous fetal startle reflex that is associated with sound stimulation most likely results in transient cord compression that is independent of amniotic fluid volume. Therefore it does not appear necessary to withhold fetal acoustic stimulation in the presence of oligohydramnios.

In conclusion, amniotic fluid volume seems to play an insignificant role in the genesis of FHR decelerations that occur after fetal acoustic stimulation.

Successful pregnancy in a patient with Hallermann-Streiff syndrome

Susan L. Hendrix, DO, and Harold J. Sauer, MD

Lansing and East Lansing, Michigan

Reproductive capacity has not been studied in patients with Hallermann-Streiff syndrome, but successful pregnancy in these patients is rare. A patient with the classic signs—plus a müllerian developmental anomaly, hypertension, glaucoma, and an extensive surgical history—was artificially inseminated, and a term gestation ensued. (Am J Obstet Gynecol 1991;164:1102-4.)

Key words: Hallermann-Streiff syndrome, uterine anomalies, pregnancy

The Hallermann-Streiff syndrome was first described in three cases, the first by Hallermann in 1948[1] and two more reported by Streiff in 1950.[2] The majority of reports appear in the ophthalmology literature.

The Hallermann-Streiff syndrome is thought to be an autosomal recessive disorder with developmental anomalies, mainly affecting the cranial and facial bones. The abnormalities most frequently seen include proportional small stature (dwarfism), craniofacial disproportion (bird facies), microphthalmia, congenital cataracts, abnormal dentition, hypotrichosis, and cutaneous atrophy of the face and scalp. There is no apparent difference in sex distribution for this syndrome and most affected patients are of normal intelligence. The literature contains scant information about the reproductive potential of affected patients, except that infertility in men is related to cryptorchidism.

Case report

A gravida 0 woman presented to the Edward W. Sparrow Hospital Outpatient Obstetrics and Gynecology Clinic for an annual examination. She expressed an intense longing for a child, and she asked about the possibility of artificial insemination with donor semen.

This patient's extensive medical history began with a diagnosis of Hallermann-Streiff syndrome in infancy. She underwent multiple tympanocenteses and at least 10 ophthalmologic procedures for treatment of glaucoma and cataracts; at presentation she was receiving pilocarpine eye drops for therapy of glaucoma. For therapy of long-standing hypertension, she took three twice-a-day medications: hydrochlorothiazide 50 mg, hydralazine hydrochloride 25 mg, and propranolol hydrochloride 50 mg. She had undergone mentoplasty at age 16 years and rhinoplasty at age 17 years.

The patient was considered to be of normal intelligence. Menarche occurred at age 14 years. She denied sexual activity and contraceptive use. She initially had

Fig. 2. A and **B,** Photographs of patient with Hallermann-Streiff syndrome showing alopecia and craniofacial characteristics.

31-day cycles and biphasic basal body temperature charts, with ovulation occurring at day 17 or 18.

Physical examination. At presentation, the patient weighed 90 pounds (41 kg) and was 4 feet 7 inches (140 cm) tall; her body stature was otherwise proportional. She has hypotrichosis for which she wears a wig (Fig. 1). Despite extensive surgery, she has obvious craniofacial disproportion. Optic examination revealed small ocular globes, narrowed palpebral fissures, and a roving nystagmus. The patient's ears are small, and the nose is small and pointed (Fig. 2, *A* and *B*).

Pelvic examination showed normal external genitalia, a narrowed introitus, and a nulliparous cervix. The uterus was anteverted and normal in size and shape; no adnexal masses were palpated. The remainder of her physical examination was unremarkable.

Diagnostic procedures and tests. Hysterosalpingography suggested a bicornuate or septate uterus with bilateral tubal patency. Follow-up intravenous urography demonstrated no abnormalities. Hysteroscopy and diagnostic laparoscopy with chromopertubation showed a subseptate uterus, left tubal patency, and failure of right tubal filling.

Clinical course. The patient was informed of the uterine anomaly and was told how it might affect her reproductive potential. She was told that, in spite of three pregnancies reported in two women with this syndrome, no previous association with müllerian anomaly had been reported and thus prognostication

Fig. 3. Phenotypically normal son of patient with Hallermann-Streiff syndrome.

was not possible. She was counseled that the inheritance was probably autosomal recessive, but that autosomal dominant transmission could not be excluded.

She conceived on her second clomiphene citrate cycle with donor insemination at the Michigan State University Clinical Center. The pregnancy was uncomplicated until term; three serial ultrasonograms showed appropriate interval growth and no apparent fetal anomalies. A fourth ultrasonogram at 38 weeks' gestation suggested a small-for-gestational age fetus. At term pelvis had a narrow interspinous diameter, and the presenting vertex fetus was ballottable. A primary low-transverse cesarean section was performed while the patient was under epidural anesthesia, and a normal, viable male infant was delivered. The child is 4 years old and is phenotypically normal (Fig. 3).

Comment

This is the first reported case of Hallermann-Streiff syndrome associated with a müllerian anomaly, the outcome of which was a successful pregnancy. Of 70 affected patients in the literature, only two women have had successful pregnancies reported. This case supports the potential reproductive capacity of patients with the syndrome and is thereby useful in counseling women with the disorder.

Fetal vibratory acoustic stimulation in twin gestations with simultaneous fetal heart rate monitoring

David M. Sherer, MD, Jacques S. Abramowicz, MD, Mary Lou D'Amico, RN, Christine B. Caverly, RN, and James R. Woods, Jr., MD

Rochester, New York

Sixteen vibratory acoustic stimulations were performed in seven normal twin gestations with continuous simultaneous recordings of each fetal heart rate response. All stimulations led to immediate synchronous fetal heart rate accelerations in both fetuses. This is in contrast to coinciding, yet nonsynchronous, spontaneous fetal heart rate accelerations that occur naturally. This observation suggests that different mechanisms are responsible for spontaneous and evoked fetal movements in twin gestations. (Am J Obstet Gynecol 1991;164:1104-6.)

Key words: Vibratory acoustic stimulation, twin gestation

Fetal movements may be spontaneous, originating within the fetus itself, or evoked, caused by external stimuli to the fetal environment. Among stimuli known to evoke fetal responses are fetal auditory, vibratory, tactile, visual and taste input, and maternal glucose intake.[1] It has been postulated that coinciding fetal heart rate (FHR) accelerations in twin gestations may represent in utero tactile communication between the two fetuses, one twin being stimulated by movements of the other.[2] To further investigate this issue we performed a prospective study involving 16 vibratory acoustic stimulations of seven twin gestations with simultaneous monitoring of each separate FHR response.

6/1/27114

Material and methods

Between July 1, 1990, and November 1, 1990, seven twin gestations were studied. Simultaneous nonstress tests of fetuses from twin gestations were performed with the following technique: with the aid of a small portable real-time ultrasonographic unit (Aloka 210, Corometrics Medical Systems, Wallingford, Conn.) with a 3.0 MHz linear transducer, fetal positioning and the location of each fetal heart were determined.

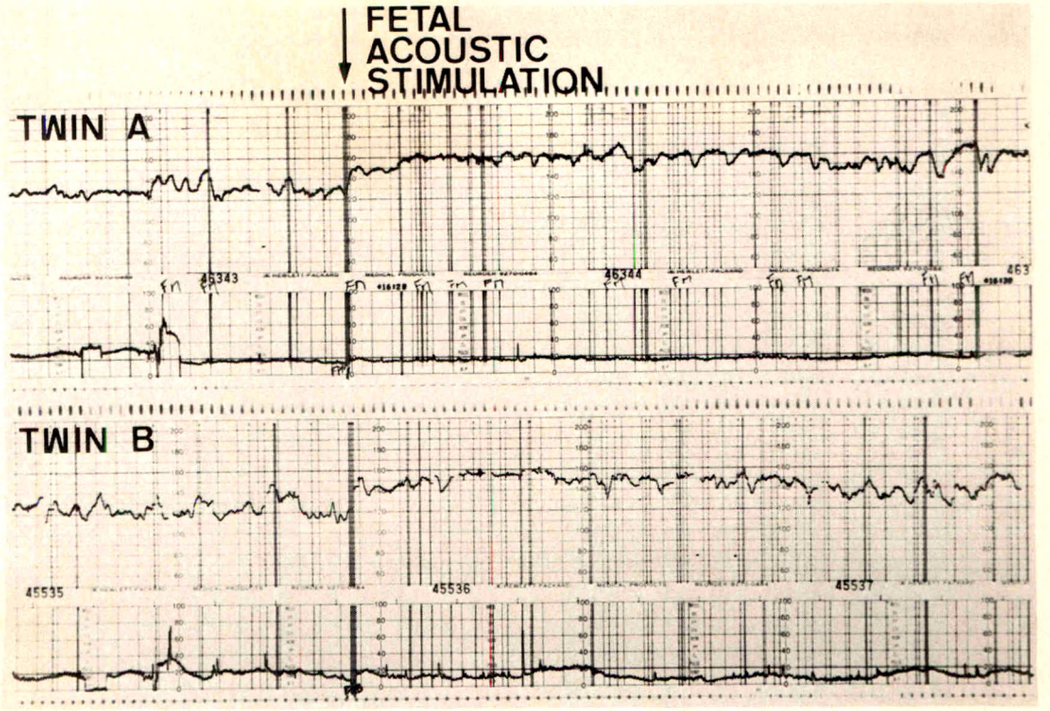

Fig. 1. Fetal vibratory acoustic stimulation of a twin gestation at 33 weeks with simultaneous electronic FHR monitoring with two separate cardiotocometers. Note the synchronous FHR accelerations of both twins in response to stimulus *(arrow)*.

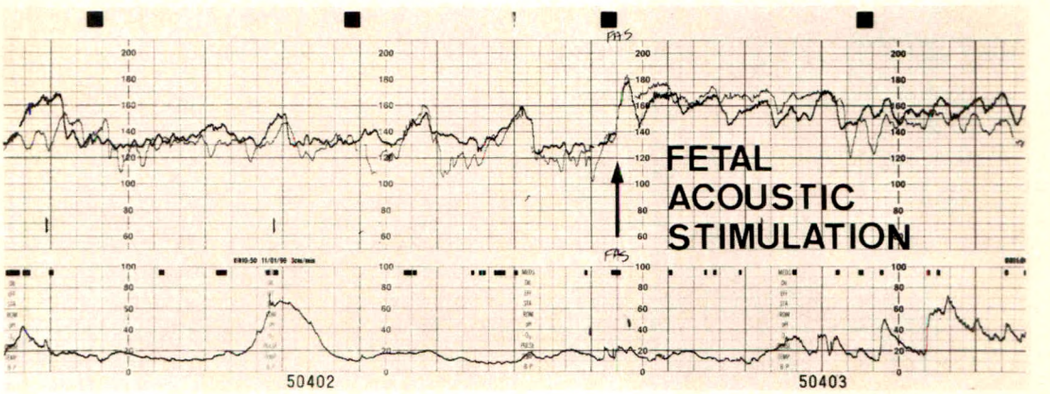

Fig. 2. Twin gestation at 37 weeks. Simultaneous FHR monitoring with a single cardiotocograph. Note two distinctly separate FHR recordings with synchronous FHR accelerations in response to stimulus *(arrow)*, as opposed to the four coinciding, yet nonsynchronous, FHR accelerations that occur spontaneously before the vibratory acoustic stimulation.

Two separate cardiotocograph machines (Hewlett-Packard Medical Products Group, Waltham, Mass., 8040A with identical ultrasonographic transducers; frequency = 1024 KHz, 15245A) or in the latter part of the study, a single cardiotocograph machine capable of performing simultaneous external FHR monitoring of twins (Hewlett-Packard M1350A with identical ultrasonographic transducers M1356A) were used. The paper speed was 3 cm/min. To assure that both fetuses were being monitored, nonidentical FHRs were verified before the stimulation. The tests were performed by a physician and a senior registered nurse. After a baseline FHR was established for each fetus, fetal vibratory acoustic stimulation was performed by applying an electronic artificial larynx (Model 5B, Western Electric, New York, N.Y., audible sounds = 750 to 1000 MHz,

vibrations between 110 and 200 Hz, output density 110 dB) for 5 seconds to the maternal abdomen directly above the maternal umbilicus.

Results

Mean maternal age was 24 ± 6 years, median gravidity was 1 (range, 1 to 3) and median parity was 0 (range, 0 to 2). Mean gestational age at the time of nonstress testing was 35 ± 2 weeks. The mean number of fetal acoustic stimulations performed on each patient was 2 ± 1 (range, 1 to 4). There was an interval of at least 1 week between stimulations in cases in which more than one vibratory acoustic stimulation per gestation was performed. Fetal presentations during the stimulations were: vertex vertex, six; vertex breech, six; breech vertex, two; breech breech, one; breech transverse, one. Mean gestational age at delivery was 36 ± 3 weeks. Mean birth weight of twin A was 2684 ± 440 gm and of twin B, 2654 ± 610 gm. Apgar scores of all 14 infants at 1 minute were ≥7.

Each of the described stimulations resulted in an immediate and synchronous acceleration of the FHR of both fetuses, irrespective of gestational age or fetal positioning (Figs. 1 and 2).

Comment

Previous studies of simultaneously recorded nonstress tests of twin gestations have revealed an association between the two separate FHR recordings. In a study of 50 twin gestations with a total of 152 nonstress tests, 57% of FHR accelerations were noted to coincide, occurring within 15 seconds of each other.[2] It was thought that this rate of coinciding FHR accelerations could be explained by the first twin's spontaneous movements causing vibration evoking a tactile response of the second twin, thereby producing fetal movements with associated FHR acceleration of the second twin. In that study, only 9% of spontaneously coinciding FHR accelerations were precisely synchronous.[2] Sadovsky,[1] in a study of 10 twin gestations with simultaneous ultrasonography of each twin, noted a 24.3% rate of simultaneous fetal movements and postulated that these represent evoked fetal movements in response to external stimuli, as opposed to the 75% of spontaneous (not simultaneous) fetal movements. Fetal acoustic stimulation, when applied to nine sets of twins, caused vigorous simultaneous fetal movements of both twins observed by ultrasonography.[1] Our documentation of the immediate synchronous FHR accelerations of both twins in response to similar stimulation supports by a different method Sadovsky's observations and suggests that different mechanisms are responsible for spontaneous and evoked fetal movements in twin gestations.

Fetal death associated with measles virus infection of the placenta

Kazuko Moroi, MD,[a] Siu Saito, MD,[b] Takeshi Kurata, MD, PhD,[c] Tetsutaro Sata, MD.[c] and Masahiko Yanagida, MD[a]

Tokyo, Japan, and Bethesda, Maryland

A case of fetal death at 25 weeks' gestation, which was associated with maternal measles infection, is described. Immunohistochemical study revealed measles virus antigen in the syncytial trophoblastic cells and decidua but not in the fetus. Results suggest that fetal death was caused by measles virus infection in the placenta. As far as we know, this is the first report in which a measles virus antigen was detected in the placenta by the immunohistochemical method. (AM J OBSTET GYNECOL 1991;164:1107-8.)

Key words: Maternal measles, placental infection, fetal death

Measles virus infection during pregnancy is rare and usually does not result in stillbirth. Thus little is known about fetal death that is caused by measles virus infection in the mother. A significant association was demonstrated between maternal measles and prematurity but not between maternal measles and spontaneous abortion.[1]

We report on a stillbirth that occurred at 25 weeks' gestation, probably because of measles virus infection of the placenta.

Case report

A 28-year-old woman, gravida 1, para 1, was referred to our hospital at the 23 weeks' gestation because of threatened abortion that was associated with high fever and skin eruptions that had continued for 3 days. Family and medical history were unremarkable, and the current pregnancy was uneventful.

At the time of admission, the patient had a fever of 40° C. Pulse rate was 130 beats/min and blood pressure was 112/60 mm Hg. Physical examination revealed dyspnea and eruptions on the face, body and thighs. The uterine fundus was consistent with 23 weeks' gestation. The cervix was closed, 60% effaced, and posterior. The slight leakage of amniotic fluid was clear. Ordinary bacterial culture of vaginal discharge was negative. Ultrasonographic examination revealed a normal-size fetus without abnormal echo and with a normal amount of amniotic fluid. The fetal heartbeat was 180 to 190 beats/min, and its pattern was reactive. Routine blood studies and kidney and liver function studies were within normal limits. Proteinuria, ketonuria, and bacteriuria were observed. Antibody titer to measles virus, which was determined by complement fixation test, changed from negative, at the time of admission, to positive (×16), on the ninth day of her illness.

The patient complained of fever, conjunctivitis, and a sore throat. She had blisters on the tongue and respiratory difficulties that were accompanied by a heart murmur. On day 9 of her illness these signs disappeared rapidly. On day 13, when she was free from almost all signs of the disease, the fetus was suddenly expelled. The stillborn infant was 650 gm, male, and normal in body shape.

The placenta was 180 gm, oval-shaped, and hard in consistency. The fetal side of the placenta was dark and the maternal side was pale and yellowish, which suggests deciduitis. Thrombosis was not found macroscopically on the cut surface of the placenta. Histologic examination revealed intervillous diffuse infiltrations of fibrin and mononuclear cells. Adhesions of the villi that were accompanied by necrosis of the trophoblastic cells were observed. The umbilical cord appeared edematous without inflammatory changes.

Measles virus antigen was demonstrated in the decidua of the placenta by immunofluorescent and immunoperoxidase methods.[2] In syncytial trophoblastic cells, the virus antigen was also clearly observed (Fig. 1). Neither inflammatory change nor measles virus antigen was found in any organs of the fetus.

Comment

As far as we know, there have been no reports that suggest an association between maternal measles and placental infection that leads to spontaneous abortion. This may be the first case of measles virus infection of the placenta that resulted in fetal death.

Placental transmission of measles virus does not seem to occur frequently.[1] In this case there was no evidence of measles virus infection in the fetus, in spite of diffuse infection of the syncytial trophoblastic cells and decidua.

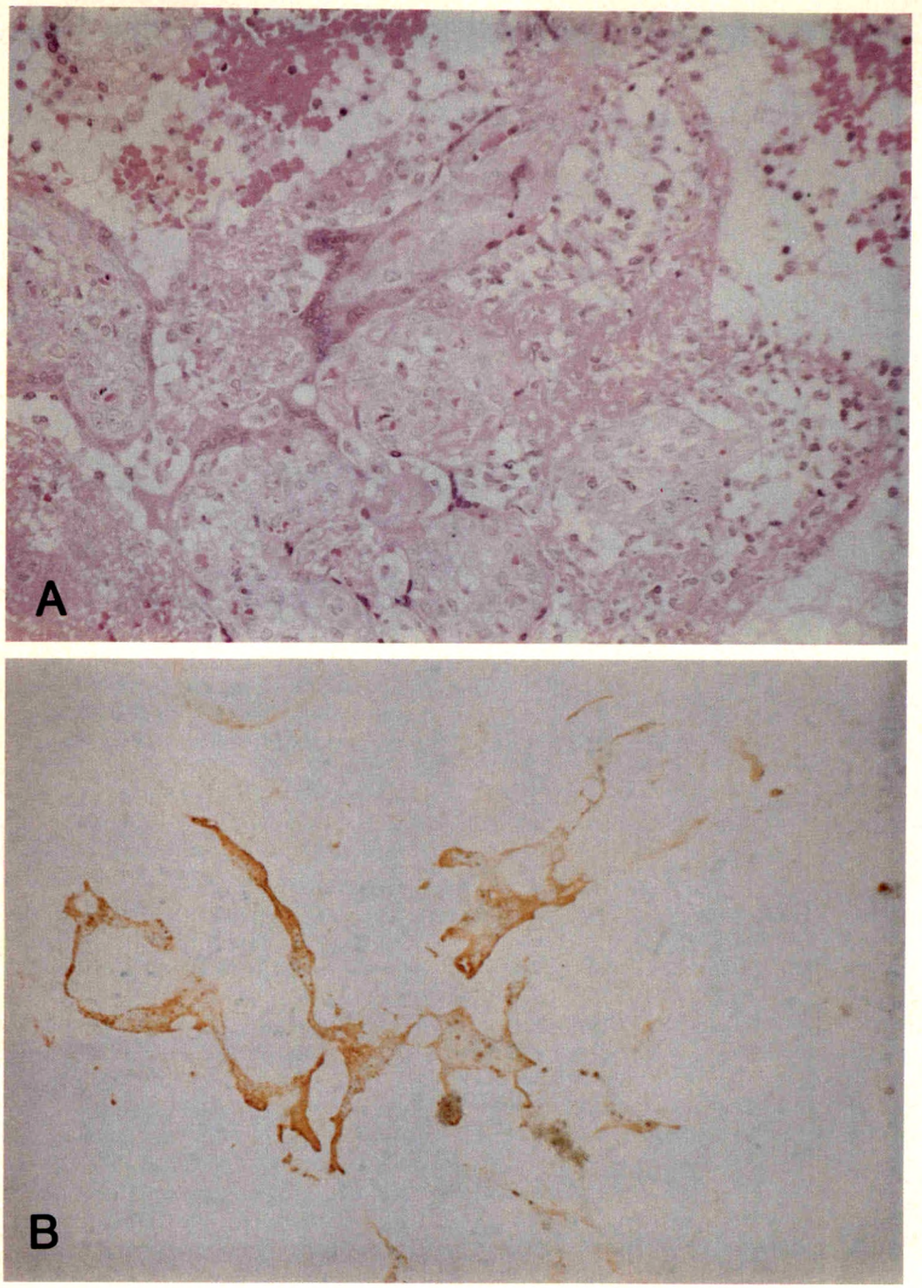

Fig. 1. Histopathologic lesion and measles virus antigen in placenta. **A**, Multinucleated cells and exudation of fibrin around chorionic villi. (Hematoxylin-eosin.) **B**, measles virus antigen in syncitial trophoblastic cells. (Immunoperoxidase.)

We suggest that fetal death was not primarily caused by fetal infection of measles virus but rather by severe placental damage, including fibrin infiltration of the perivascular and intervillous spaces of the placenta. These changes may decrease intravillous blood flow and oxygen supply to the fetus, which cause fetal death or distress that probably produces uterine contractions.

Coffee during pregnancy: A reproductive hazard?

Steven A. Narod, MD, Silvia de Sanjosé, MD, PhD, and Cesar Victora, MD, PhD
Lyon, France, and Pelotas, Brazil

Coffee is consumed in large quantities worldwide and any adverse effects would likely have important public health consequences. Because of the widespread exposure to coffee and other caffeine-containing beverages and because teratogenic effects of caffeine have been recorded in several species since 1960, women are concerned that there may be reason to limit their intake of coffee when pregnant. Several human studies on birth defects have been conducted and the overall results do not implicate coffee as a likely human teratogen. However, there is some evidence that consumption of three or more cups of coffee per day may have a modest effect on lowering infant birth weight. Studies of coffee consumption and increased rates of spontaneous abortion and delayed time to conception are inconsistent and conclusions cannot yet be drawn. (AM J OBSTET GYNECOL 1991;164:1109-14.)

Key words: Coffee, caffeine, congenital malformation, spontaneous abortion, birth weight, infertility

Coffee has international social and medical acceptance and is a leading commodity of world trade. In the United States consumption is estimated at 4.5 kg per person per year, or 1.7 cups per day (an average of 3.3 cups per coffee drinker).[1] However, the highest consumption of coffee is recorded in Finland, with 12.2 kg per person per year. Many women now decrease their coffee intake when pregnant,[2] possibly in response to several publicized reports of adverse reproductive effects including congenital malformations, decreased birth weight, spontaneous abortion, and reduced fertility. Recently a meeting was conducted at the International Agency for Research on Cancer in Lyon, France, to evaluate the carcinogenic risks of caffeine-containing beverages. The epidemiologic and laboratory-based evidence for adverse effects of coffee on several aspects of human health, including reproduction, was reviewed.[5]

Caffeine is the predominant pharmacologically active component of coffee and is responsible for its stimulating effect. Caffeine is also used to stimulate spermatozoa in vitro with the hope of increasing the conception rate in artificial insemination.[4] The concentration of caffeine in coffee varies according to the method of preparation, making international epidemiologic studies difficult. In North America a typical cup of brewed or percolated coffee contains roughly 100 mg of caffeine. Other caffeine-containing beverages include tea (40 mg per cup) and most cola beverages (20 mg per 10-ounce serving).

Caffeine was shown to be a teratogen in mice in 1960.[5] Since that report, adverse developmental effects of caffeine were confirmed in several species including mice, rats, and rabbits; these effects were recently reviewed[6] and are not discussed here in detail. Mice are susceptible to cleft palate and abnormalities of the digits including ectrodactyly (absence of fingers) at doses of caffeine >50 mg/kg per day (equivalent to about 25 cups of coffee per day or roughly two to five times higher than the highest consumption levels regularly reported by pregnant women). Ectrodactyly appeared in rabbits at doses >100 mg/kg per day.[7] In most teratology studies effects were seen only at >50 mg/kg per day (i.e., at doses in which maternal toxicity was common).

The reports of defects in mice induced by caffeine naturally raised concern about the possibility of similar effects in human beings. In 1980, on the basis of the animal evidence, the U. S. Food and Drug Administration cautioned pregnant women to limit their intake of coffee.[8] A considerable amount of epidemiologic data were collected since then and we are now in a better position to use information about human exposures to judge the need for such a warning.

Congenital malformations

In 1981 three cases of children with ectrodactyly were born to women who admitted to drinking large

From the Unit of Mechanisms of Carcinogenesis and the Unit of Field and Intervention Studies, International Agency for Research on Cancer, and the Department of Social Medicine, University of Pelotas. 6/1/25240

amounts of coffee during pregnancy.[9] Some limb malformations may be relatively minor, but ectrodactyly is clearly a serious defect; in some a "lobster-claw" or "split-hand" malformation is present. Ectrodactyly may be seen in combination with a cleft palate and may appear in several members of a family; however, the majority of cases occur sporadically and have no known cause.[10]

Three large-scale epidemiologic studies[11-13] published in 1982 and in 1983 failed to support this anecdotal finding. In Finland, coffee was drunk in greater quantities during pregnancy by mothers of children born with congenital malformations, when compared with local control mothers.[11] These negative results are consistent with those of most other studies. Linn et al.[12] interviewed 12,205 pregnant women in the Boston area from 1 to 2 days after delivery. Major malformations were documented in 2.5% of the women who reported no coffee or tea use during pregnancy and in 2.0% of heavy coffee drinkers. In the third study[13] mothers of 2030 malformed infants in Boston, Philadelphia, and Toronto were also questioned about coffee drinking in pregnancy. The level of consumption did not vary significantly for children with malformations of different organ systems.

More recently, Tikkanen and Heinonen[14] reported on coffee consumption in the mothers of 569 children born with cardiovascular malformations in Finland between 1982 and 1984 and in 1052 control mothers. Eighty-two percent of mothers in both the case and control groups reported drinking coffee during pregnancy.

The positive evidence to date for a possible teratogenic effect of coffee in human beings comes from two less rigorous studies. In an early Belgian case-control study, the mothers of 190 children with birth defects drank an average of 28 cups of coffee per week during pregnancy, three cups more than the 175 control mothers.[15] However, 44 mothers in the case group (23.2%) drank more than 8 cups per day versus 21 mothers in the control group (12.9%; $p < 0.05$). The odds ratios for heavy coffee drinkers can be calculated for several malformations including ventricular septal defect [odds ratio (OR), 23.5], cleft lip (OR, 4.5), hypospadias (OR, 4.8), Down syndrome (OR, 3.0), and limb defects (OR, 1.7).

The second positive study is from Japan[16]; 9921 healthy pregnant women were asked about coffee consumption at 24 weeks' gestation. The rate of congenital anomalies in coffee drinkers (3.7%) was more than twice as great as the rate in nondrinkers (1.7%). Surprisingly, the authors fail to comment on this highly significant ($p < 0.001$) difference, and state instead, "The rate of congenital anomalies was not significantly different among the five groups."[16] Elevated rates were seen for cardiac malformations [relative risk (RR), 1.9], cleft palate (RR, 2.4), polydactyly (RR, 2.9), multiple malformations (RR, 21.5), chromosomal abnormalities (RR, 14.0), and miscellaneous anomalies (RR, 1.8). Many of the details that the reader would like to see are missing from this provocative report. It is noteworthy that in both positive studies malformations as a result of chromosomal abnormalities were increased among children of heavy coffee drinkers. If the alleged association with coffee were causal, then the beverage would qualify both as mutagen and teratogen—a simpler explanation is that a hidden bias is elevating rates of malformations of all types.

Although ectrodactyly was not specifically analyzed in the three high-quality reports (probably because of the rarity of the condition), positive associations with skeletal anomalies as a group were not found. However, very few women were exposed regularly to large amounts of coffee (e.g., eight or more cups per day), and because of the possibility of a threshold level for teratogenic effects in human beings, the safety of coffee consumption at high levels cannot be inferred from studies of predominantly low or moderate coffee drinkers.

Incidence data on specific congenital anomalies for 10 European countries are compiled and published by the EUROCAT project.[17] There appears to be little correlation between the frequency of abnormalities of the limbs and average coffee consumption (as determined by the International Coffee Organization[1]) among the 17 contributing registries. Correlation coefficients obtained by combining data from these two sources can be calculated for coffee consumption and limb reduction defects (−0.065), syndactyly (0.435), polydactyly (0.201), and all limb deformities combined (0.0122). Denmark, with the highest per capita coffee consumption recorded for any of the participating countries (10.83 kg per person per year), had the highest rate of all limb anomalies (possibly a reflection of the high rates of reporting in the country).

In summary, at levels commonly consumed during pregnancy, epidemiologic studies do not support the animal data that coffee may be a human teratogen. The findings of the two discrepant studies deserve mention although their data should probably be reexamined at this time.

Birth weight

Low birth weight (defined here as <2500 gm) is the most extensively studied reproductive effect in relation to coffee. Infant birth weight is easy to measure, is measured routinely, and is a meaningful measure because it correlates with infant mortality and morbidity. In developed countries, the majority of low-birth-weight babies are preterm, but other causes are re-

Table I. Summary of studies of coffee and birth weight

Study	*Risk study population*	*Principal factors adjusted for*	*Results*
Watkinson, Fried[3]	286	Smoking, education	Decreased birth weight among consumers of >300 mg per day*
Linn[12]	12,205	Alcohol, smoking	<4 cup/day, RR = 1.0 ≥4 cup/day, RR = 1.2†
Furuhashi[16]	9,921	None	<5 cup/day, BW = 3163 gm >5 cup/day, BW = 3081 gm*
Mau, Netter[19]	5,200	Alcohol, maternal age	Nondrinkers, RR = 1.0 Occasional, RR = 1.4 Frequent, RR = 1.6*
VandenBerg[20]	15,000	Smoking, reproductive history	≤1 cup/day, RR = 1.0 2-6 cups/day, RR = 1.4 ≥7 cups/day, RR = 2.2*
Kuzma, Sokol[21]	5,093	Gestational age, weight gain, ethnic group, smoking	Decreasing birth weight with increasing coffee intake*
Martin, Bracken[22]	3,891	Gestational age, ethnic group, parity, smoking, alcohol	No caffeine, RR = 1 1-150 mg, RR = 1.4 151-300 mg, RR = 2.3 >300 mg, RR = 4.6*
Munoz[23]	48	Smoking, alcohol, gestational age	Average decrease of birth weight of 121 gm for drinkers of >450 ml/day vs none
Caan, Goldhaber[24]	267	Ethnic group, alcohol, parity, smoking, weight	Nondrinkers, RR = 1.0 >300 mg/day, RR = 2.8†
Brooke[25]	1513	Gestational age, height, parity, smoking, sex of baby	0-200 mg, BW = 3664 gm 200-400, BW = 3609 mg† >400, BW = 3556 gm†

BW, Birth weight.

†Not significant.

sponsible for about one third. The study of low birth weight is complicated by the many demographic, medical, social, and behavioral characteristics that influence it, and coffee consumption has been associated with several of these. In particular, smoking, a known risk factor for low birth weight, may be positively correlated with coffee intake.[12] Not all studies have considered these important relationships. It should be noted that the probability of a low-birth-weight baby having a more serious developmental outcome varies with the cause of the low birth weight. Children small for dates born to smoking mothers, for example, may be less likely to have long-term growth problems than babies born with a similar birth weight as a result of other causes.[18]

Current evidence of an association between coffee (and other caffeine-containing beverages) and low birth weight is summarized in Table I. Smoking was controlled for in eight of the 10 reports. An inverse relationship between coffee consumption and birth weight was seen in some degree in all studies, and on seven occasions the association was statistically significant. Relative risks of being delivered of an infant who weighs <2500 gm ranged from 4.6 to 1.2 for drinkers of more than tree cups of coffee per day. The mean decrease in birth weight in the positive studies ranged from 70 to 121 gm—values slightly lower than those reported as a result of smoking (roughly a 150 to 200 mg reduction).[26]

Among these reports three studies have not been reviewed elsewhere. The most relevant is a comprehensive study from New Haven, Connecticut,[22] of 3891 women who attended selected antenatal care centers. Total caffeine consumption was estimated for these women from reported intake of coffee, tea, and cola drinks at home interviews during pregnancy. Pregnancy outcomes were determined from hospital records. After controlling for age, ethnic group, parity, and smoking, caffeine intake >300 mg per day (equivalent to three cups of coffee a day) was associated with a 4.6-fold increase in low birth weight in comparison with nondrinkers [95% confidence interval (CI) 2.0 to 10.5]. A dose-dependent response with increasing consumption was seen. Coffee intake was also associated with low socioeconomic status, smoking, and alcohol intake. The effect of caffeine on birth weight was limited to term infants.

In a case-control study in California[24] low-birth-weight babies were more common to mothers who drank more than three cups of coffee daily during the

first trimester. After adjusting for ethnicity, alcohol, smoking, prepregnancy weight, weight gain, and parity the risk was elevated (RR, 2.8) but was not statistically significant (95% CI, 0.89 to 8.69).

Brooke et at.[25] studied 1513 pregnant women in London. After correcting for gestational age, maternal height, parity, sex of the baby, and smoking they found no relationship between the mean birth weight and coffee consumption.

Earlier studies of coffee and infant birth weight were reviewed elsewhere.[27-28] Overall, the data on coffee consumption during pregnancy suggest a small effect on reduction of birth weight. This effect is most likely to be relevant for women who are already at risk of having a low-birth-weight infant by virtue of other medical and social factors.

Spontaneous abortions

An association between coffee consumption and spontaneous abortion was found in three studies reviewed,[16, 29, 30] but not in three others.[2, 31, 32] Srisuphan and Bracken[29] interviewed 3135 women during their pregnancies (for methods see reference 22). They found a 70% increase in miscarriage at between 8 and 26 weeks' gestation in moderate coffee drinkers compared with nondrinkers after correcting for differences in maternal age, gestational age, previous spontaneous abortions, and other gynecologic surgery ($p = 0.03$).

Furuhashi et al.[16] reported an increase in the rate of spontaneous abortions from 1.2% to 2.0% for mothers who drank coffee during their pregnancies ($p < 0.001$). The methodologic limitations encountered in this study were mentioned previously.

The study by Weathersbee et al.[30] is much cited, no doubt because of its dramatic results. Eight hundred obstetric patients were identified in Utah and southern Idaho in 1974 and 1975, of whom 489 completed a mailed questionnaire. Sixteen women reported coffee intake >600 mg daily. Eight of the 16 pregnancies ended in miscarriage, five in stillbirth, and two in premature births. Unfortunately, the authors sampled from a group of women hospitalized because of a variety of obstetric reasons, and the rates reported are difficult to interpret. A more meaningful analysis would have been to compare coffee levels among samples of women with miscarriages and other reasons with control patients who had normal deliveries. In some cases, women were asked to complete the questionnaire 2 years after pregnancy of interest.

Watkinson and Fried[3] found no differences in the mean caffeine intake between women who had miscarriages and those with normal deliveries, although a higher proportion of coffee drinkers were found among mothers who miscarried. Krsnjavi and Mimica[31] in Yugoslavia and Ardanova and Katsulov[32] in Bulgaria reported no relationship between the rate of spontaneous abortions and coffee drinking. In most studies pregnant women have been recruited from prenatal clinics and therefore any effects of coffee on very early miscarriage will be missed.

Fertility

Recently, attention has been drawn to a possible effect coffee may have on delaying fertility.[33-36] A series of 124 women who had not become pregnant by 3 months after discontinuation of birth control were questioned with regard to habitual coffee consumption and were then monitored for the next 12 menstrual cycles or until they became pregnant.[33] A total of 452 cycles were analyzed; with a life-table approach the authors calculate that 28% of high coffee consumers (>31.5 cups of coffee per month) were unable to achieve pregnancy in the first year versus 6% for women who consumed less than this amount. The probability of becoming pregnant in a given month in the group with high coffee consumption ranged from 32% to 88% of that of the more moderate drinkers. A second study[34] with a much larger number of women (2817) was unable to confirm the alleged relationship between coffee consumption and conception. The average reported time to conception was 4.4 months for women who drank three or more cups per day versus 4.6 months for those who drank less than one cup per day. The overall patterns of fertility were similar in the two centers where the studies were performed and there is no apparent reason why the results of the two studies should be so discrepant. In the original study the amount of coffee consumed was recorded before conception, whereas in the second study consumption levels were determined retrospectively. However, because of the larger number of participants in the second study it should probably be given greater weight. The findings of Wilcox et al.[33] prompted a second look at a data set that was generated from the interviews of more than 6000 pregnant women before 1967.[35] Women who reported having had trouble getting pregnant were almost twice as likely to be high consumers of coffee (four or more cups per day) than were those without this difficulty, but significance figures are not provided. In a similar manner the records of 3010 married women living in Massachusetts who were delivered of a single infant between 1977 and 1980 were reviewed.[36] Mean time to conception was longer for women who drank four or more cups of coffee a day (6.65 months) than for women who did not drink coffee (4.84 months). For women who consumed four or more cups of coffee a day average fecundability (calculated monthly) was 81% of that of those who did not drink coffee, after adjusting for age, parity, weight, alcohol, tobacco, and marijuana use ($p < 0.05$). These four studies raise an

interesting hypothesis, but an association is yet to be proved. It is hoped that further data will be available soon.

Comment

The epidemiologic data assembled to date on congenital malformations and coffee consumption during pregnancy do not confirm the teratogenic associations observed in mice. To date associations in human beings are largely anecdotal, although it is recognized that little data are available on consumers of very high amounts of coffee during pregnancy, that a threshold effect is possible, and that if a teratogenic effect were limited to very rare malformations (e.g., ectrodactyly) these may be missed in studies of birth defects as a group. The studies reviewed vary in quality. In general it was not possible to verify the amount of coffee reported to be consumed by the pregnant women and in some cases women were asked to recall habits of several years past. It may be that the women with poor outcomes were more likely to overestimate these amounts.

Although evidence is limited, coffee drinkers may be at higher risk of having a baby of low birth-weight. On the basis of the data it is probably wise to reduce coffee consumption during pregnancy to a moderate level, for example not more than 2 cups of percolated coffee per day, especially for women who are at risk of a low-birth-weight infant because of other reasons. Because fetal growth is most rapid during the third trimester this may be the period of greatest sensitivity, but the studies conducted so far have not tested this hypothesis specifically. Three of four studies on fertility reported delayed time to conception among women who drank moderately large amounts of coffee. Although further evidence is needed to confirm this association, it is probably reasonable to suggest to women who have difficulty in becoming pregnant that they limit their coffee intake. The evidence is so far insufficient to support an association between coffee drinking and spontaneous abortion.

In summary, the need for a warning for pregnant women to limit their coffee drinking is probably justified, although amounts normally consumed by pregnant women in the United States likely are safe. It is not clear whether the effect on birth weight is due entirely to caffeine or to other components of coffee. Because of the increasing use of decaffeinated beverages this may be a question for future research.

Bound volumes available to subscribers

Bound volumes of the American Journal of Obstetrics and Gynecology are available to subscribers (only) for the 1991 issues from the Publisher, at a cost of $61.00 for domestic, $88.27 for Canadian, and $84.00 for international for Vol. 164 (January-June) and Vol. 165 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the Journal name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular Journal subscription.

A new model for objective assessment of cervical ripening: The effect of prostaglandin E_2 and prelabor contractility

Toru Takahashi, MD,[a] Beth Marcus, BA,[b] Richard G. Scheerer, MD,[b] and Michael Katz, MD[b, c]

Kawasaki, Japan, and San Francisco, California

A rabbit cervix preparation designed to evaluate the effects of locally administered substances and those of prelabor contractility on cervical ripening is described. In one experiment, one of the two cervices was exposed to prostaglandin E_2 gel and the contralateral cervix was exposed to plain gel. In another experiment, one cervix was completely isolated from prelabor contractility, whereas the contralateral cervix remained intact. Cervical ripening was assessed by measurement of the stretch modulus and rate of creep 2 days later. Treatment with prostaglandin E_2 gel and exposure to prelabor contractility resulted in significant unilateral cervical changes, suggesting that at least part of the prostaglandin E_2 effect is locally mediated and that spontaneous prelabor contractility may play a role in cervical preparation for labor. Furthermore, because of its simplicity, this animal preparation can be useful in the investigation of the effects of other locally administered substances on cervical ripening. (AM J OBSTET GYNECOL 1991; 164:1115-8.)

Key words: Cervical ripening, rabbit, prelabor contractility, prostaglandin E_2, local effect

The effect of locally applied hormones on ripening of the uterine cervix has been well documented by numerous investigators.[1-4] However, it remains unclear whether the effect occurs directly through local diffusion or indirectly by triggering events in sites remote from the cervix, which eventually may result in cervical ripening. For example, vaginal prostaglandin application may initiate subtle myometrial activity[5] that in turn affects cervical status. To distinguish direct from indirect effects, we designed an animal model that permits two cervices to undergo different manipulations while under the influence of the same systemic environment. In this article we describe our initial experiments with this new animal preparation, which was designed to evaluate the effects of local manipulations on cervical ripening. The manipulations in this study include the local application of prostaglandin E_2 (PGE_2) and the isolation of one cervix from prelabor uterine contractility.

Material and methods

Ten New Zealand White rabbits, weighing 4 to 5 kg and with known dates of conception, were used. Guidelines for animal use were approved by the Research and Human Experimentation Committee and the Animal Care Subcommittee of our institution. We studied only animals in which the number of fetuses in each horn was similar (difference of two or fewer). On 27 to 28 days' gestation (term is 31 days), the uterine horns were exposed through a lower abdominal midline incision after induction of general anesthesia with ketamine (20 mg/kg per hour) and xylazine (4 mg/kg per hour). Induction of local anesthesia with 1% lidocaine was used for skin and peritoneal incisions. The two cervices and the proximal half of the vagina were separated by use of a surgical stapler (TA 55 surgical stapling instrument, United States Surgical Corporation, Norwalk, Conn.) as shown in Fig. 1. Preliminary studies with the use of this preparation on a few animals showed that the surgery did not interfere with the animals' capability of spontaneous delivery at term. Experiments were designed to evaluate the effects of either local PGE_2 application (group 1, $n = 5$) or prelabor uterine contractility (group 2, $n = 5$) on cervical ripening. In group 1, 1 ml of gel containing 0.25 mg of PGE_2 was applied to the portio vaginalis cervicis of one side and 1 ml of plain gel was applied to the other. In group 2 the uterine horn on one side was separated from the cervix so that prelabor contractions descend-

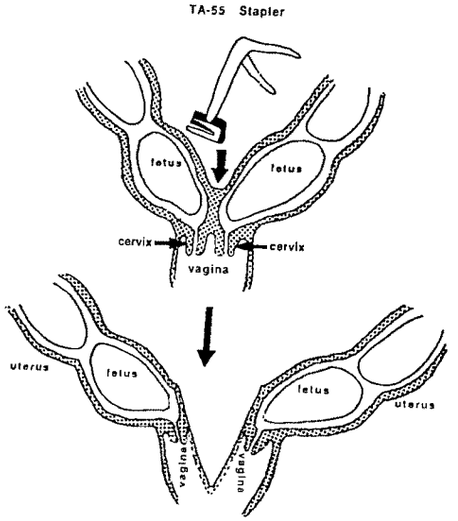

Fig. 1. Schematic presentation of two cervices and the proximal half of the vagina separated by use of a surgical stapling instrument.

ing from that side would not reach the cervix (Fig. 2). The manipulations were alternated between left and right sides in successive experiments. A third set of experiments was done to determine cervical distensibility in the nonpregnant rabbit in early pregnancy and post partum. In these animals, no gel was applied to the cervix.

Two days later (day 29 to 30) the animals were anesthetized with pentobarbital (30 mg/kg) and laparotomy was performed. After confirmation of fetal viability the cervices were removed and cut transversely into several 1.5 mm wide rings. Two central rings from each cervix were randomly assigned to one of two tests of tensile properties. One method, which was initially described by Harkness and Harkness[6] and then modified by Hollingsworth and Isherwood,[7] applies a constant load to the cervix and measures the increments in length plotted against time. This method (the creep test) defines cervical extensibility as equal to $10^3K/L_o$, where K is the rate of increase in inner circumference during the slow deformation (millimeters per minute) and L_o is the inner circumference in millimeters at time zero. This formula provides a measure of the rate of increase in cervical diameter corrected for variations in cervical size.

The second method we used to evaluate cervical ripening was the stretch modulus in which cervical distensibility is determined by continuous measurement of the tension that is created while stretching the specimen at a constant rate.[8] Cervical ring stretch modulus is calculated from the linear part of the time-tension curve with the formula $E = (T/A)/(L/L_o)$, where E is the stretch modulus in milligrams per square millimeter, A is the cross section of the analyzed sample in square millimeters, T is the recorded tension in milligrams, L is the length increment in millimeters, and L_o is the unstressed initial length in millimeters.

Means and SDs were calculated for each of the two methods of cervical assessment, and comparisons between the control and experimental sides were done by the Wilcoxon paired-sample test.

Results

The differences in the rate of creep and stretch modulus between the control and experimental sides for the PGE_2 studies confirmed the presence of a significant effect. The mean rate of creep for the PGE_2-treated side was 3.47 ± 1.41 min^{-1} as compared with 2.01 ± 1.17 min^{-1} for controls ($p < 0.05$). The mean stretch modulus for the PGE_2-treated side was 4250 ± 1360 mg/mm^2 as compared with 7580 ± 3560 mg/mm^2 ($p < 0.05$) for controls. Rate of creep was higher and stretch modulus was lower for the PGE_2-treated cervices of each animal.

In the second group of experiments in which one cervix was separated from the uterine body, the mean rate of creep for the control intact cervices (exposed to prelabor contractions) was 4.23 ± 2.25 min^{-1} as compared with 2.98 ± 1.58 min^{-1} for the separated cervices (not exposed to prelabor contractions, $p < 0.05$). The mean stretch modulus for control intact cervices (6090 ± 3490 mg/mm^2) was significantly lower than that observed for the separated cervices (8760 ± 2990 mg/mm^2). The higher rate of creep and lower stretch modulus values were observed in the intact cervix in each of the experiments.

For comparison, in the nonpregnant rabbit, rate of creep was 1.05 ± 0.27 and increased to 1.66 ± 0.22 in early pregnancy (7 days' gestation), increased further to 5.05 ± 1.00 at 29 to 30 days' gestation, then fell to 1.91 ± 0.60 at 7 days post partum. Similarly, stretch modulus was 5890 ± 1640 in nonpregnant rabbits, fell to 4040 in early pregnancy, was 3280 ± 1450 at 29 to 30 days' gestation, and was 3240 ± 1380 at 7 days post partum.

Comment

Our data for control cervices show that even with timed pregnancies and vigorously controlled conditions there are significant individual variations in cervical characteristics among animals. This fact stresses the potential difficulties in comparison of the effects of drugs or uterine contractility on the cervix between animals and points to the potential advantage of our preparation, which uses each animal as its own control.

In this study we were interested in the way PGE_2 affects cervical ripening. Mackenzie and Embrey[9] showed by use of tocodynamometry that cervical ap-

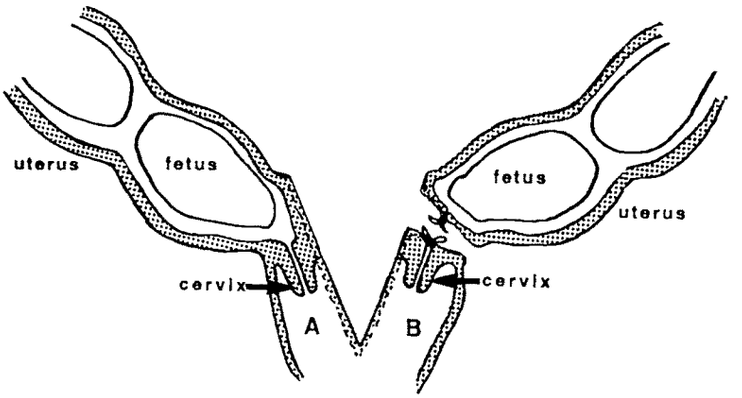

Fig. 2. Uterine horn on one side is separated from the cervix so that the cervix is not exposed to prelabor contractility descending from that side.

plication of PGE_2 in human beings can be associated with quick systemic absorption of the hormone, leading to increased uterine contractility. However, what proportion, if any, of the PGE_2-induced ripening can be attributed to a local effect or an increase in contractility is not clear. If PGE_2 were to initiate cervical ripening only through contractions, then one would expect that both cervices would be equally affected in our preparation. However, the significant differences in cervical ripening that we observed confirmed that at least part of the PGE_2 effect is local.

A second aspect of cervical ripening is that of a possible effect brought about by prelabor uterine activity. Stys[10] recorded intracervical pressures in ewes at term and concluded that cervical ripening preceded the onset of that uterine activity, which was characteristic of labor, by 12 hours. Liggins et al.[11] infused PGE_2 into the uterine artery of sheep and reported cervical ripening with relatively little uterine activity. However, until now there were no animal models available to evaluate whether the relatively low amplitude prelabor uterine activity plays a role in cervical ripening. Furthermore, even if uterine pressure is recorded, cervical changes depend to a significant extent on a variety of systemic hormonal changes that occur just before the onset of labor.[12] In this study, in which the systemic environment was identical for both cervices, exposure to prelabor uterine activity was shown to be associated with a significantly more compliant cervix than that observed with a nonexposed cervix. Whether prelabor uterine activity in human beings also affects cervical ripening in the same manner is not completely clear. However, research by Alvarez and Caldeyro[13] documented a gradual increase in prelabor contractility several weeks before birth, the time shown to be associated with cervical ripening in women.[14] It is thus conceivable that prelabor contractility may also be an important factor in cervical ripening in human beings, and that this effect may be in addition to other systemic hormonal influences.

Although PGE_2 has been shown to cause cervical ripening independent of uterine activity,[15] there is ample evidence to confirm that cervical ripening and myometrial maturation for labor occur in concert with each other.[16] Whereas these events may be mostly of an academic interest at term, they could have clinical significance during the preterm period. Namely, if excessive premature low-amplitude uterine contractility can lead to accelerated cervical ripening, inhibition of this type of activity before the onset of active labor could be potentially beneficial. Furthermore, we speculate that if a relationship between prelabor contractility and cervical ripening can be established, investigations to clarify the mechanism behind such a phenomenon could help find treatments to either prevent premature ripening of the cervix or enhance ripening in postdate pregnancies.

Evaluation of changes in umbilical blood flow in the fetal lamb by Doppler waveform analysis

Klaus G. Schmidt, MD,[a, b] Mariarosaria Di Tommaso, MD,[b] Norman H. Silverman, MD,[a] and Abraham M. Rudolph, MD[a, b]

San Francisco, California

Doppler velocity waveform analysis from descending aortic and umbilical artery signals was performed in 14 instrumented fetal lambs when umbilical blood flow was altered acutely. Blood flow was increased and reduced (by cord occlusion or placental embolization) and ranged 14% to 168% and 8% to 132% from baseline values in the descending aorta and the umbilical artery, respectively. When flow was severely reduced (<50% of baseline value), mean placental resistance increased almost fourfold and mean heart rate fell by 30% from baseline levels. There were only weak correlations between Doppler waveform indices and actual flow, which were usually not significantly different from the correlations between Doppler indices and actual heart rate. With both cord occlusion and placental embolization, significant changes of index values from baseline values were seen only when flow was severely reduced. We conclude that Doppler waveform analysis is not sensitive enough to detect acute mild to moderate reductions in placental flow. Increased index values with severely reduced flow may be explained in part by the concomitant fall in heart rate. (Am J Obstet Gynecol 1991;164:1118-26.)

Key words: Prenatal diagnosis, fetal echocardiography, fetal diseases

Doppler velocity waveform analysis of the umbilical artery[1-3] or descending aortic blood flow[4, 5] has been proposed as a noninvasive method to study the placental circulation in the human fetus. Several indices that are derived from the peak systolic, mean, and end-diastolic velocity are in clinical use, and the method has been widely applied to assess fetal well-being and to predict neonatal outcome.[6-8] Increased indices have been related to reduced umbilical blood flow as a result of increased placental vascular resistance.[9] In clinical studies, the indices that were derived from Doppler waveform analysis have usually been related to markers of fetal well-being or outcome of pregnancy such as fetal growth, pH level, or Apgar score at delivery. However, the mechanisms that may lead to changes of the indices are incompletely understood.

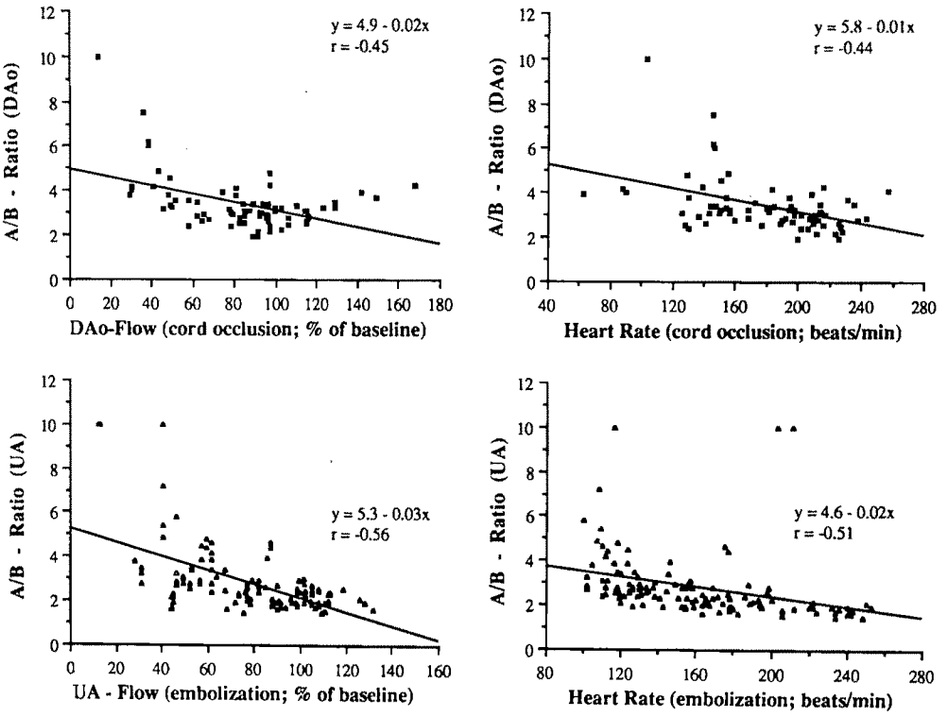

Fig. 1. Examples of the correlation between Doppler waveform indices—here the systolic/diastolic *(A/B)* ratio—and invasively measured blood flow *(left panels)* or fetal heart rate *(right panels)*; *upper panels* refer to descending aortic signals *(DAo)* in the cord occlusion experiment, and *lower panels* refer to umbilical artery signals in the placental embolization experiment. There are weak correlations between index values and reductions of flow, which are similar when index values are related to heart rate.

Only a few experimental studies have approached these questions.[10, 11] We therefore designed this study to investigate the acute influence of alteration of placental flow and resistance on Doppler waveform analysis with three different indices, which were derived from velocity tracings at the descending aortic and umbilical arterial levels.

Methods

Surgical preparation. We studied 14 pregnant sheep of mixed Western breed at 127 ± 3 days of gestation (term = 150 days) with fetuses that weighed 3.0 ± 0.6 kg. The ewes were fasted for 24 hours before surgery. After they had undergone epidural anesthesia by injection of 4 ml of 1% tetracaine, polyvinyl catheters (1.27 mm internal diameter) were placed into a pedal artery and vein of each ewe. Fluids (10% dextrose in 0.9% saline solution, 3 to 5 ml/min) and ketamine (100 mg every 10 to 15 minutes) for maternal sedation were given intravenously. The uterus was exposed through a midline incision, and a hysterotomy was performed on the proximal portion of the pregnant horn. Anesthesia for all fetal surgery was achieved by administration of 0.5% lidocaine. A fetal hind limb was exposed, and polyvinyl catheters (0.76 mm internal diameter) were inserted into the anterior tibial artery and vein and advanced to the lower descending aorta and inferior vena cava, respectively. Next, the other hind limb and rump were extracted through the same hysterotomy, and the left fetal flank was exposed. An incision was made anterior to the spinal muscles along the lower lumbar vertebral column. The abdominal muscles were carefully dissected; the lower descending aorta and common umbilical artery were exposed as described previously.[12]

Two electromagnetic flow transducers (C&C Instruments, Culver City, Calif.) of appropriate size were placed on the descending aorta just proximal to the iliac bifurcation and on the common umbilical artery. In each of eight animals, a polyvinyl catheter (0.4 mm internal diameter) was placed in a small branch of the iliac artery so that its tip was in the common umbilical artery, which allowed an embolization of the placental vascular bed with plastic microspheres; two other cath-

eters (0.76 mm internal diameter) were then inserted into a cotyledonary vein and advanced into the central umbilical vein. The other six animals had neither of these catheters inserted, but each had a balloon occluder placed around the umbilical cord. All incisions were closed, and each fetus was returned to the uterine cavity. A catheter with multiple side holes was inserted into the amniotic cavity, and the uterine incision was closed after lost amniotic fluid had been replaced with warmed 0.9% saline solution.

Experimental protocol. The fetuses were studied immediately after surgery. Fluid-filled catheters were connected to Statham P 23Db pressure transducers (Viggo-Spectramed Inc., Critical Care Div., Oxnard, Calif.), which were calibrated to the nearest millimeter of mercury with a static mercury column. Mean and phasic aortic pressures as well as mean amniotic, umbilical, and inferior vena caval pressures were measured. Fetal heart rate was obtained from a cardiotachometer linked to the phasic aortic pressure recording. Mean and phasic descending aortic and umbilical blood flows were monitored with the electromagnetic flow probes with Statham SP 2202 flowmeters. Pressure and flow tracings as well as heart rate were recorded continuously with a Beckman eight-channel direct-writing recorder (Beckman Instruments, Inc., Fullerton, Calif.). A blood gas analysis (model 158, Corning Medical, Medfield, Mass.) was obtained before the study and after each experimental alteration of blood flow.

Measurements were taken at baseline values; then umbilical blood flow was increased by intravenous administration of atropine and norepinephrine (0.1 mg/kg and 1 μg/kg/min, respectively) to the fetus. Subsequently, umbilical blood flow was decreased either by stepwise occlusion of the cord ($n = 6$) or by embolization of the fetal side of the placental vascular bed ($n = 8$) with repeated injections of 2×10^6 plastic microspheres (25 μm in diameter, 3M Company, St. Paul, Minn.) into the common umbilical artery.

Actual descending aortic and umbilical flow was measured at each step with the radionuclide-labeled microsphere technique.[13] Labeled 15 μm microspheres (selected from gadolinium 153, cobalt 57, indium 114, chromium 51, stannum 113, strontium 85, niobium 95, manganese 54, zinc 65; Du Pont Diagnostic Imaging Div., Billerica, Mass.) were injected into the inferior vena cava, while a reference sample was withdrawn from the descending aorta at a rate of 4 ml/min for 1.25 minutes (at least 40 seconds after completion of the microsphere injection). Removed fetal blood was measured and replaced with an equal volume of fetal donor blood or maternal blood.

At the end of the experiment, the ewe and fetus were killed by an overdose of pentobarbital and subsequent bilateral thoracotomy was performed in accordance with the guidelines of the Committee on Animal Research of the University of California, San Francisco. The fetus was weighed and dissected; the lower carcass (below L4-5) and the uterus and cotyledons were weighed and placed in formalin. The tissues were car-

bonized in an oven at 350° C, pulverized, and placed into plastic vials to equal height. The radioactivity of tissues and reference blood samples was counted in a 1000-channel multichannel pulse-height analyzer (Norland Corp., Fort Atkinson, Wis.). The specific activity of each isotope within a sample was calculated by the least-squares method.[14] Descending aortic and umbilical blood flow (Q) was calculated according to the formula: Q = (Reference flow × Organ counts)/Reference counts. Electromagnetic flowmeter readings of descending aortic and umbilical flow were adjusted to the microsphere measurements; they served as flow measurement at any time between microsphere determinations. In lambs that underwent placental embolization, the peripheral vascular resistance (R) was calculated as: R = (Mean aortic − Mean inferior vena caval pressure)/Flow.

Doppler ultrasonographic study. Pulsed Doppler interrogation of the descending aorta and the umbilical artery was performed several times at each step of altered descending aortic and umbilical flow. We used an ATL Mark 600 instrument (Advanced Technology Laboratories, Inc., Bothell, Wash.) with a 5 or 3 MHz mechanical transducer that was placed directly on the uterine horn that contained the instrumented fetus. Images of the fetal descending aorta and the umbilical cord were obtained in all animals. The Doppler sample volume was placed in the lower descending aorta or in the umbilical cord close to the site at which it enters the fetal body until high-pitched acoustic signals of the pulsatile flow were heard, and an optimal signal was displayed by the spectral output. Ultrasonographic evaluation was recorded continuously on half-inch videotape for later analysis. Time registration by means of recording paper speed and the internal clock of the ultrasonographic machine allowed off-line comparison of the Doppler indices with the measured physiologic variables at one time.

Off-line analysis of the Doppler tracings was performed with a computer-assisted analysis system and commercially available software (CAD 886, Microsonics, Indianapolis). Peak systolic, least diastolic, and mean velocities were measured from the maximum spectral display of the Doppler shift that was sampled in the fetal descending aorta and umbilical artery. Doppler waveform indices were calculated as:

Systolic/diastolic (A/B) ratio = Peak systolic/End-diastolic velocity

Pulsatility index = (Peak systolic − End-diastolic velocity)/Mean velocity

Resistance index = (Peak systolic − End-diastolic velocity)/Peak systolic velocity

Five consecutive beats were averaged for each index determination. For the systolic/diastolic ratio, a value of 10 was considered maximum and was also assumed if end-diastolic velocity was zero.

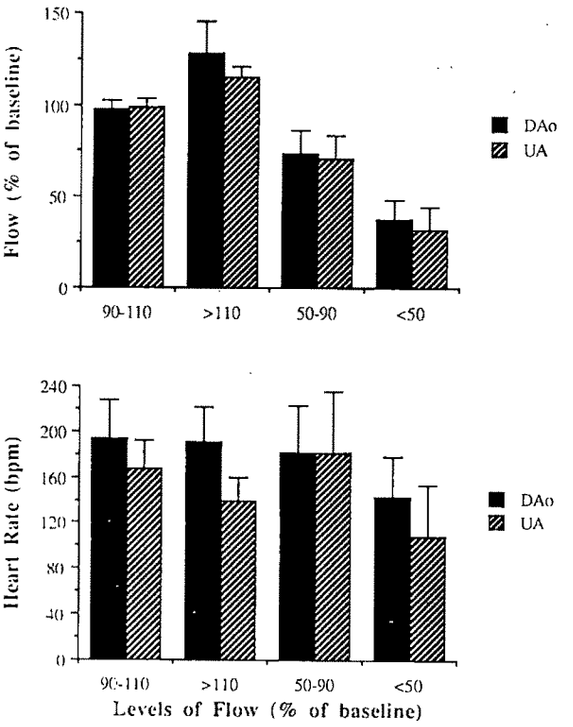

Fig. 2. In the cord occlusion experiment, increases and reductions of mean flow (+SD) at the three levels of altered flow that were measured in both the descending aorta *(DAo)* and umbilical artery *(UA)* are shown *(top)*. Simultaneous changes in heart rate also are shown *(bottom)*.

Statistics. Data are given as mean ± SD. The descending aortic and umbilical blood flow alterations were expressed as percent from baseline flow in each animal. Linear regression analysis was used to correlate both blood flow and heart rate with Doppler waveform indices that were obtained simultaneously. Student's *t* test was used to compare the slopes of the regression lines.

For further analysis the actual flow measurements were assigned to one of four levels of flow: 90% to 110% was considered to be baseline flow, >110% increased flow, 50% to 90% moderately decreased flow, and <50% severely decreased flow. Measured physiologic variables and calculated Doppler waveform indices were pooled according to these levels of flow both in the cord occlusion and in the placental embolization protocols. Analysis of variance was used to assess differences at the different levels of flow for each Doppler waveform index. If the null hypothesis had to be rejected, multiple comparisons between different levels

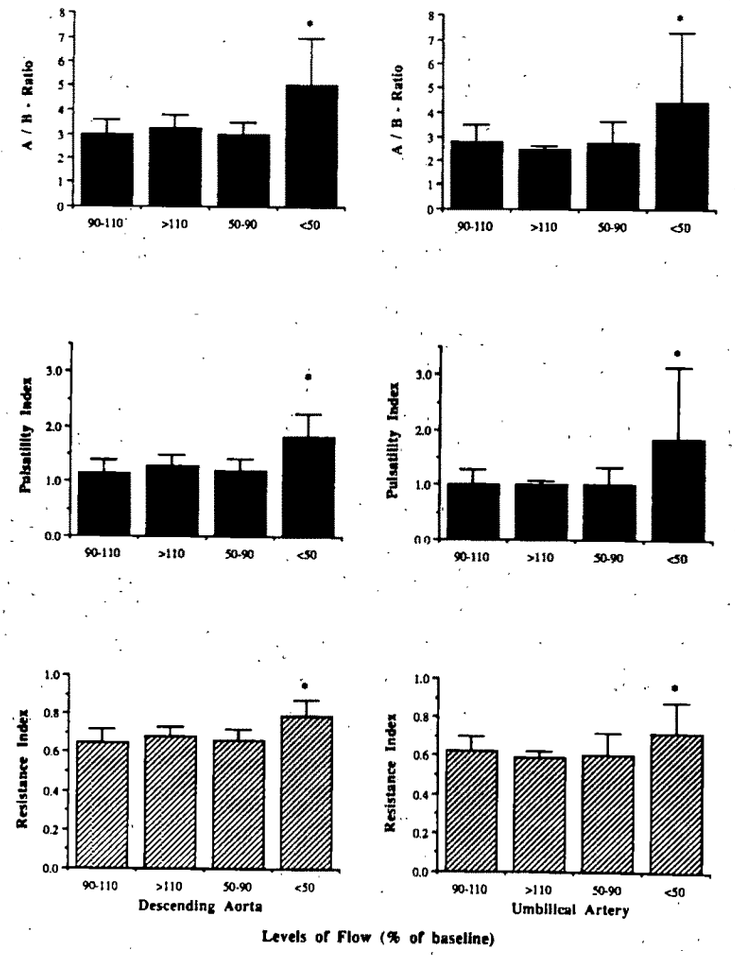

Fig. 3. Doppler waveform indices in the cord occlusion experiment as assessed at baseline and at three levels of altered flow in both the descending aorta *(left)* and umbilical artery *(right)*. Indices shown are systolic/diastolic *(A/B)* ratio *(top)*, pulsatility index *(middle)*, and resistance index *(bottom)*. Significant changes from baseline only occurred in the group with severely reduced flow *(asterisk,* $p < 0.05$).

of flow were made by the Scheffé method; $p < 0.05$ was considered to indicate a significant difference between groups.

Results

Cord occlusion. In the cord occlusion experiment, blood flow alterations, which were expressed as percent from baseline flow, ranged from 14% to 168% in the descending aorta and from 8% to 124% in the umbilical artery. The three Doppler waveform indices that were tested showed considerable variability at all levels of flow; with severely reduced flow, index values tended to increase. There were weak correlations between flow and index values over the range of flow alteration (Fig. 1, top left). There was, however, a similar trend if index values were correlated with heart rate (Fig. 1, top right). The slopes of the regression lines for index values versus blood flow did not differ significantly from those for index values versus heart rate (Table I).

At each level of alteration, mean flow was significantly different from baseline flow; with severely compromised flow, it was decreased to 38% ± 10% from baseline in the descending aorta and to 34% ± 13% from baseline in the umbilical artery (Fig. 2). Concomitantly, there was a significant fall in heart rate from 194 ± 34 to 143 ± 35 beats/min (descending aorta) and from 181 ± 55 to 108 ± 45 beats/min (umbilical artery) when the baseline and severely reduced flow levels were compared. Over these ranges of altered blood flow, Doppler waveform indices were determined on 74 oc-

casions from descending aortic velocity tracings and on 84 occasions from umbilical arterial velocity tracings. Significant changes of the three Doppler waveform indices from their respective baseline values were only noted when flow was reduced to <50% of baseline (Fig. 3); this observation was made for the Doppler indices that were obtained from both the descending aortic and umbilical artery velocity tracings.

Placental embolization. In the placental embolization experiment, blood flow alterations ranged from 21% to 135% in the descending aorta and from 13% to 132% in the umbilical artery. As in the cord occlusion experiment, there were weak correlations between flow and index values over the range of flow alteration, and index values also correlated weakly with heart rate (Fig. 1, bottom). The slopes of regression lines that correlated index values with blood flow or heart rate did not differ significantly except for the systolic/diastolic ratio, which was obtained from umbilical artery signals (Table I). At each level of alteration, mean flow was significantly different from baseline flow. At the severely compromised flow level, it decreased to 39% ± 10% from baseline in the descending aorta and to 42% ± 9% from baseline in the umbilical artery (Fig. 4). Concomitantly, there was a significant, almost fourfold increase in the peripheral vascular resistance and significant decreases in fetal heart rate and fetal pH (Fig. 4). Mean heart rates fell from 169 ± 36 beats/min at baseline to 131 ± 27 beats/min (descending aorta) and from 178 ± 30 to 131 ± 29 beats/min (umbilical artery) when flow was severely reduced (<50% of baseline). Over the ranges of altered blood flow, Doppler waveform indices were determined on 72 occasions from descending aortic velocity tracings and on 129 occasions from umbilical arterial velocity tracings. Significant mean changes of the three Doppler waveform indices from their respective baseline values were only noted when flow was reduced to <50% of baseline (Fig. 5); this observation was made for the Doppler indices that were obtained from both descending aortic velocity tracings and umbilical artery velocity tracings.

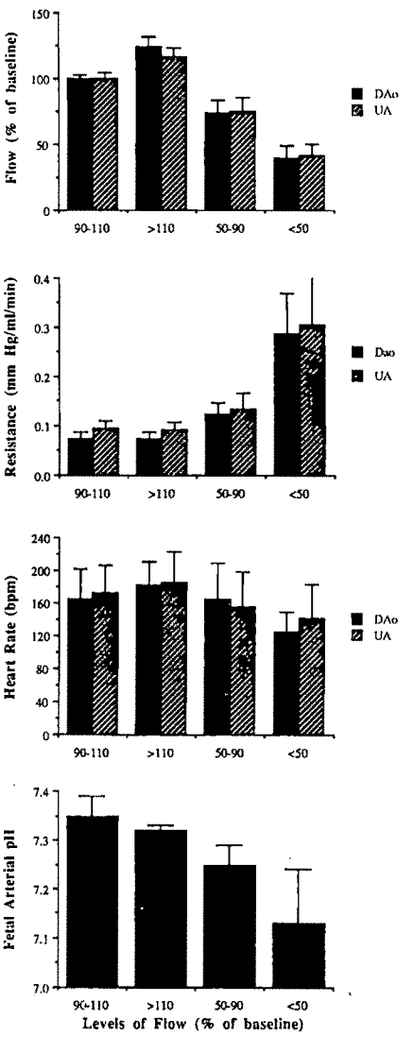

Fig. 4. In the placental embolization experiment, increases and reductions of mean flow (+SD) at three levels of altered flow that were measured in both the descending aorta *(DAo)* and umbilical artery *(UA)* are shown *(top)*. Simultaneous increase in placental vascular resistance *(upper middle)* and decrease in heart rate *(lower middle)* are also shown. With reduction in blood flow, fetal arterial pH values were significantly reduced *(bottom)*.

Comment

Our study demonstrates that Doppler waveform indices that are obtained from descending aortic and umbilical arterial velocity tracings are not sensitive enough to detect mild to moderate acute changes of blood flow. Although we altered umbilical blood flow considerably (Figs. 2 and 4), mean index values that were obtained both from descending aortic signals and umbilical arterial signals changed significantly from baseline values only when blood flow was severely reduced to <50% of baseline; a similar observation was made when umbilical blood flow was reduced both by venous and by arterial obstruction of the fetal side of the placental circulation when mechanical occlusion to the cord or arterial embolization was employed (Figs. 3 and 5).

Both modes of obstruction to umbilical blood flow may occur and may lead to placental dysfunction in human fetuses as well. Whereas cord occlusion causes venous congestion of the placental vascular bed, embolization causes obstruction at the level of small co-

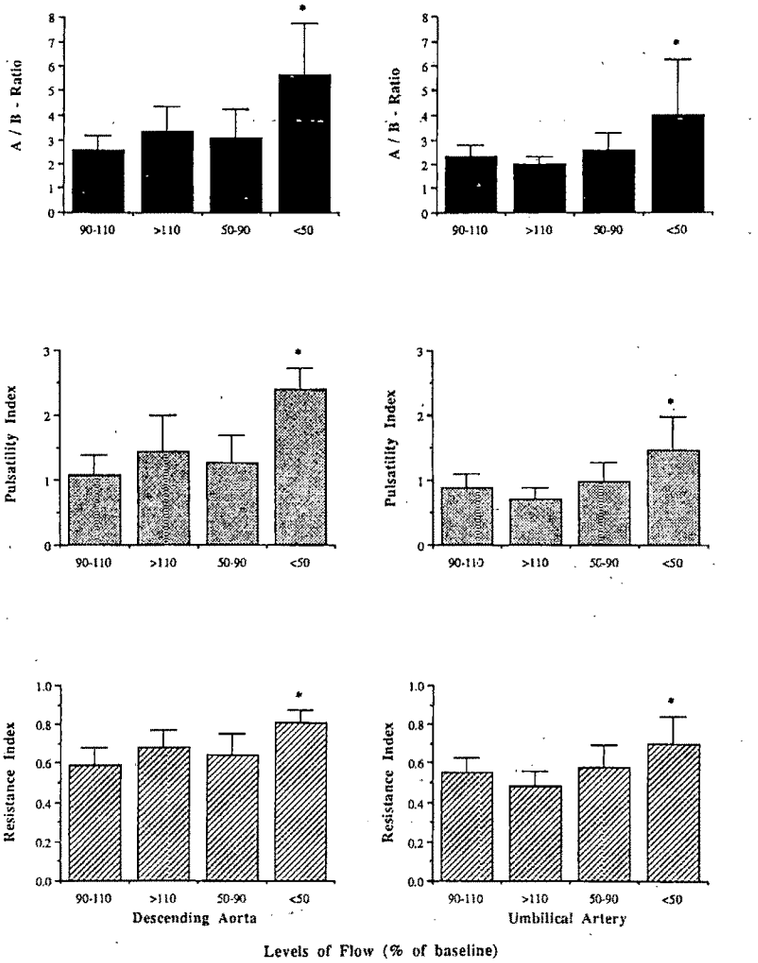

Fig. 5. Doppler waveform indices in the placental embolization experiment as assessed at baseline and at three levels of altered flow in both the descending aorta *(left)* and umbilical artery *(right)*. Indices shown are systolic/diastolic *(A/B)* ratio *(top)*, pulsatility index *(middle)*, and resistance index *(bottom)*. Significant changes from baseline occurred only in the group with severely reduced flow (*asterisk*, $p < 0.05$).

tyledonary arteries with a concomitant increase in placental vascular resistance. In human fetuses the suggestion has been frequently made that increased placental vascular resistance causes increased Doppler waveform indices.[1-6] High placental resistance was attributed to a loss of small arteries that are found in the placenta when high index values had been observed in these fetuses.[9] In our embolization experiment, however, moderate increases in placental vascular resistance, which raised it to a mean of 140% to 165% from baseline value, did not significantly change the Doppler waveform indices. This finding suggests that early changes in the placental vascular bed that lead to an increase in resistance are not detected by Doppler waveform analysis.

Only after an increase in resistance to almost 400% of baseline level did mean index values increase significantly, but even then, many index values were still found in the range that is seen at the baseline level (Fig. 1). Accordingly, the standard deviations of index values in the severely compromised flow groups increased considerably (Figs. 3 and 5). Sometimes we also observed high index values at the baseline flow level; other reports have related such variability of Doppler waveform indices to the use of different instruments for the ultrasonographic studies[15] or to considerable interobserver variability,[16] but we used the same ultrasonographic machine for all studies and had one observer, who was blinded to actual flow measurements, interpret all of the studies. Whatever the cause, this study dem-

onstrates a considerable variability of Doppler waveform indices at normal and compromised flow levels, which limits its usefulness in detection of the fetus that is at impending risk for the development of significant placental dysfunction.

In the recent experimental study by Trudinger et al.,[10] an observed increase in the systolic/diastolic ratio was related to a moderate rise of the placental vascular resistance as a result of chronic embolization of the fetal umbilical arteries. In this study, however, the mean values of the systolic/diastolic ratio ranged between 2 and 2.5 both in control and treated animals; these values represent a normal range that would not allow identification of a condition of increased placental vascular resistance in a general population. The authors also state that heart rates in control and treated animals did not change over the course of the experiment.[10] This finding is very different from our own and those of other researchers,[11] who observed a decreasing fetal heart rate after placental embolization; this discrepancy remains unexplained. According to our results, heart rate is significantly related to an increase of index values when umbilical flow is reduced. The weak correlations that we found between actual flow and simultaneous index values were similar to those that were obtained when index values were plotted against heart rate; most commonly, the slopes for these regression lines were not significantly different from each other, which suggests that increased index values can also be related to the reduced heart rate.

Several clinical reports have linked increases in Doppler waveform index values mainly to simultaneous slowing in heart rate.[17, 18] This seems reasonable because the fetus with a slower heart rate has a longer diastolic period and a lower end-diastolic velocity in the descending aorta or umbilical artery; lower end-diastolic velocity, in turn, will lead to higher index values. Other researchers, however, have found little[19] or no effect[20] of fetal heart rate on Doppler waveform indices. Van Huisseling et al.[21] recently demonstrated in fetal lambs that pulsatility index increased during fetal hypoxemia that was induced by obstruction of the maternal common iliac artery without change in placental resistance; however, pulsatility index remained unchanged when fetal heart rate was held constant by parasympathetic blockade. The authors conclude that increasing index values are mainly related to slowing of fetal heart rate but not to placental resistance.[21]

Among all combinations tested, the index values that were obtained from umbilical artery velocity signals in the embolization experiment showed the best correlation with actual flow (Table I). This may be significant for the clinical situation in which umbilical arterial signals rather than descending aortic signals should be used; umbilical arterial Doppler signals may also be found more easily than descending aortic signals. Furthermore, all three indices that were tested provided similar results when different modes of flow reduction and variable sites of Doppler interrogation were considered. Therefore there seems to be no special advantage in the use of one index instead of another. Because the systolic/diastolic ratio requires minimal computation, it may be the best index to use in the clinical situation, if there is indeed a need to do so. The parameters that determine vascular resistance are complex and multifactorial. Because the calculation of fetal descending aortic and umbilical blood flow with the Doppler technique has been shown to be reasonably accurate[22] and useful in the clinical situation,[23] such flow measurements may provide an alternative to the Doppler waveform indices.

Immunohistochemical localization of gonadotropin-releasing hormone during implantation in the New Zealand White rabbit

Paul A. Bergh, MD,[a] Ted L. Anderson, PhD,[b] and Glen E. Hofmann, MD, PhD[a]

New York, New York, and Nashville, Tennessee

Gonadotropin-releasing hormone was localized immunohistochemically during implantation (gestational days 6 to 14) in the New Zealand White rabbit. During early implantation (days 7 to 9), intense gonadotropin-releasing hormone immunostaining was localized predominantly to the cytoplasm of the nonknob cytotrophoblast with light to moderate staining in the cytoplasm of the syncytiotrophoblast (knob). In later gestation, light to moderate staining of the cytoplasm of the trophoblast at the true placental site was detected. No appreciable change in staining was noted after day 10. Fetal membranes, identified after day 10, showed intense and unchanging immunostaining for gonadotropin-releasing hormone. Obplacental giant cells showed light to moderate nuclear and cytoplasmic gonadotropin-releasing hormone immunostaining. Light to moderate gonadotropin-releasing hormone immunostaining was also noted in the cytoplasm of uterine epithelium and glands. We conclude that immunoreactive gonadotropin-releasing hormone is present in the cytotrophoblast at the time of the earliest embryo-uterine interactions and may play a significant role in implantation and embryo survival. (AM J OBSTET GYNECOL 1991;164:1127-31.)

Key words: Gonadotropin-releasing hormone, implantation, trophoblast, immunohistochemistry

The decapeptide, gonadotropin-releasing hormone (GnRH), is found in the arcuate nucleus of the hypothalamus, and its pulsatile release controls gonadotropin secretion from the pituitary gland.[1] A GnRH-like substance that is immunologically and biologically similar to hypothalamic GnRH has been shown in the placenta of many species including rabbits and human beings.[2,3] In human placenta, this GnRH-like substance appears to be involved in the control of the synthesis and secretion of the gonadotropin, human chorionic gonadotropin (hCG).[4-6]

A paracrine function has also been postulated for GnRH in the rabbit related to early embryo-uterine interaction and nidation[7]; hence it would be useful to study the presence of GnRH-like substance in the periimplantation and early postimplantation trophoblast as the embryo prepares to adhere to and implant in the uterine epithelium. For obvious practical and ethical reasons, studies involving the use of periimplantation trophoblast cannot be carried out in human subjects. Therefore because the temporal, physiologic, and morphologic aspects of nidation are well characterized in the rabbit,[8-10] this model was used to localize and describe the expression of GnRH-like activity during implantation. A distinctive feature of the rabbit blastocyst is the appearance of discrete islands of trophoblastic knobs (syncytiotrophoblast) dispersed throughout the cytotrophoblast (nonknob). Previous studies localized GnRH-like activity in human placenta predominantly to the cytotrophoblast, along the outer surface layer of the syncytiotrophoblast, and in the villous stroma.[11] Thus the configuration of the rabbit placenta provides a unique opportunity to examine potential roles for GnRH in the initial stages of trophoblastic differentiation and implantation. Immunohistochemistry was used to characterize the expression of a GnRH-like substance by the very earliest trophoblast and to clarify a possible role in embryo-uterine interactions.

Material and methods

Adult New Zealand White rabbits were used for these studies. They were caged individually in an American Association of Accreditation of Laboratory Animal Care–accredited facility on an alternating 12-hour light and dark photography period with free access to food and water. Mating of the animals, uterine perfusion and fixation, and implantation site processing for light microscopy and immunohistochemistry were performed as previously described.[12] The day of mating was defined as day zero.

Immunohistochemical localization of GnRH-like fac-

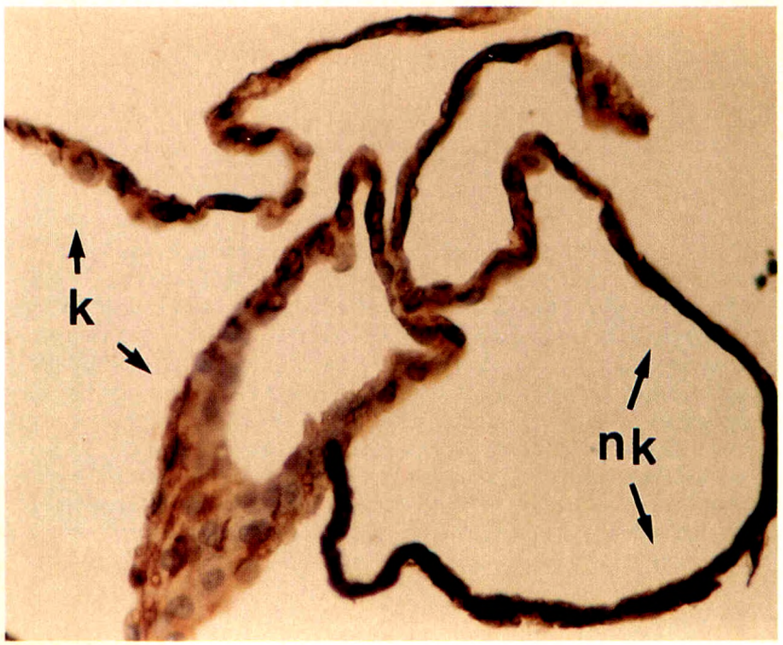

Fig. 1. Early implantation site (day 8), GnRH immunostaining is very intense and is localized predominantly to the cytoplasm of cytotrophoblast (*nk*). Moderate staining of the cytoplasm of the syncytiotrophoblast (*k*) is also noted. (×350).

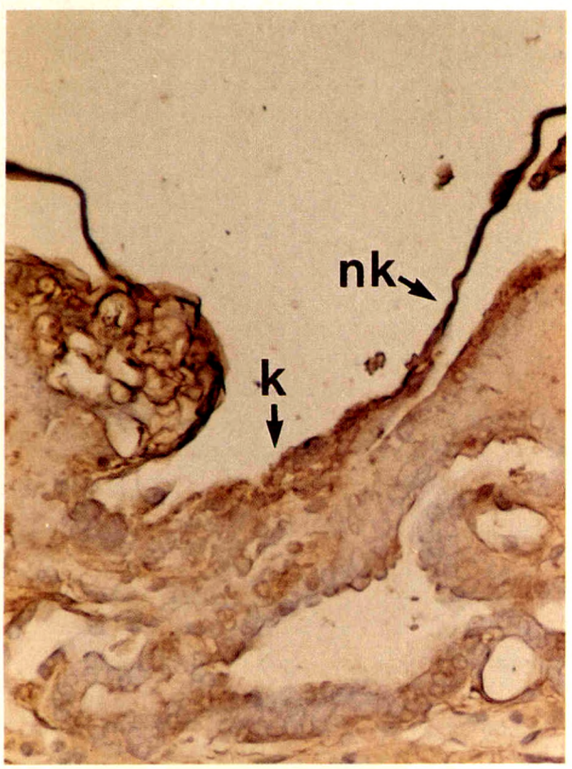

Fig. 2. Early implantation site (day 8). Differential staining of cytotrophoblast (*nk*) is maintained as the syncytial knob (*k*) fuses with uterine epithelium. Knob shows only light staining. Note staining of the uterine epithelium and glands. (×350).

tor was accomplished on 5 μm paraffin-embedded sections with polyclonal sheep anti-GnRH No. 94 (generously provided by Dr. H. M. Fraser, Edinburgh, Scotland). The specificity of this antibody is directed against the C-terminal end of GnRH. Cross-reactivity with fragments of GnRH remained at 100% after the removal of up to 3 N-terminal amino acids, whereas cross-reactivity dropped to <0.01% with the replacement at position 10 of Gly-NH_2 by Gly-OH or with the use of other brain peptides.[13] The specificity of this antibody against the high molecular form(s) of GnRH has not been established (unpublished observation). Immunohistochemical localization of the GnRH-like substance was performed by the ABC method (Vector Laboratories, Burlingame, Calif.) with the peroxidase substrate, 3,3′-diaminobenzidine (Sigma Chemical Co., St. Louis). The protocol used was as follows: endogenous peroxidases were blocked with 1% hydrogen peroxide in methanol. Nonspecific binding was blocked by incubation with 10% normal serum. Tissues were then incubated overnight (4° C) with the primary antibody diluted to 1:1000 in phosphate-buffered saline solution with 5% bovine serum albumin (Sigma Chemical Co.). The tissues were then washed in phosphate-buffered saline solution and the biotinylated antibody applied. The slides were then lightly counter-stained with hematoxylin. In control incubations, identical sections were treated in the same fashion except that the primary (anti-GnRH) or secondary (biotinylated) anti-

body were excluded or the primary antibody was preabsorbed with the native GnRH (Sigma Chemical Co.) at a final concentration of 1 μmol/L. First-trimester human placenta served as a positive control. In addition, antiserum was diluted in phosphate-buffered saline solution with 1%, 5%, 10%, and 15% bovine serum albumin to assess the possibility that the antiserum recognized the bovine serum albumin to which the GnRH was conjugated during immunization of the sheep. At least two animals were studied at each gestational day (6 through 14) and at least two different implantation sites from each animal were examined.

Immunohistochemical staining was recorded as absent, light, moderate, or intense. All results were correlated with the gestational age of the implantation sites.

Results

Immunoreactivity for the GnRH antibody was detected in all sections from each gestational day studied. In early implantation sites (days 7 to 9), GnRH immunostaining was very intense and was localized predominantly to the cytoplasm of the nonknob cytotrophoblast. Light to moderate staining was noted in the cytoplasm of the syncytiotrophoblast (knob); however, no nuclear staining was detected (Fig. 1). This differential staining pattern was maintained after fusion of the syncytial knob with the uterine epithelium (Fig. 2). In later implantation sites (days 10 to 14), light to moderate GnRH immunostaining was identified in the true placenta (Fig. 3). Fetal membranes (identified from day 10 onward) stained more intensely than did the placenta (Fig. 3). Immunostaining of placenta and fetal membranes was unchanged on all gestational days studied (days 10 to 14). Obplacental giant cells showed light to moderate nuclear and cytoplasmic immunoreactive GnRH staining (Fig. 4). Light to moderate GnRH immunoreactivity was detected in the uterine surface epithelium, stroma, and glands (Fig. 2) both before and after fusion of the trophoblast with uterine epithelium. Immunostaining was not observed in nonimplantation sites, resorption sites, and nonpregnant uteri. Also, no immunostaining was seen in the control experiments in which either antibody was excluded or the primary antibody was preabsorbed with GnRH. First-trimester human placenta showed intense GnRH immunostaining as described previously.[11] Immunostaining was not affected by changes in the percentage of bovine serum albumin, suggesting the antibody did not recognize any portion of the bovine serum albumin (not shown).

Comment

In human beings, exogenous GnRH has been found to stimulate production of hCG and release by placental tissue and cells in vitro.[4-6] The hCG produced by the placenta is required to rescue the corpus luteum thus ensuring adequate progesterone production needed for complete endometrial decidualization and successful nidation. Immunofluorescence has located the placental GnRH-like peptide predominantly to the cytotrophoblast, making this the most likely site of production.[11] Thus it is theorized that placental GnRH or a related substance derived from the cytotrophoblast may effect hCG production and secretion by acting on trophoblast receptors perhaps located on the syncytiotrophoblast cell membrane.[11] Further support of this relationship is offered by the observation that maternal serum levels of hCG correlate very closely with the existing number of cytotrophoblasts. The localization of GnRH along the outer surface of syncytiotrophoblast cell membrane is consistent with the mechanism of action of a peptide hormone.[14] These findings led to speculation that the placenta may function in a manner analogous to the hypothalamic-pituitary-gonadal axis and may possess its own GnRH-mediated hCG regu-

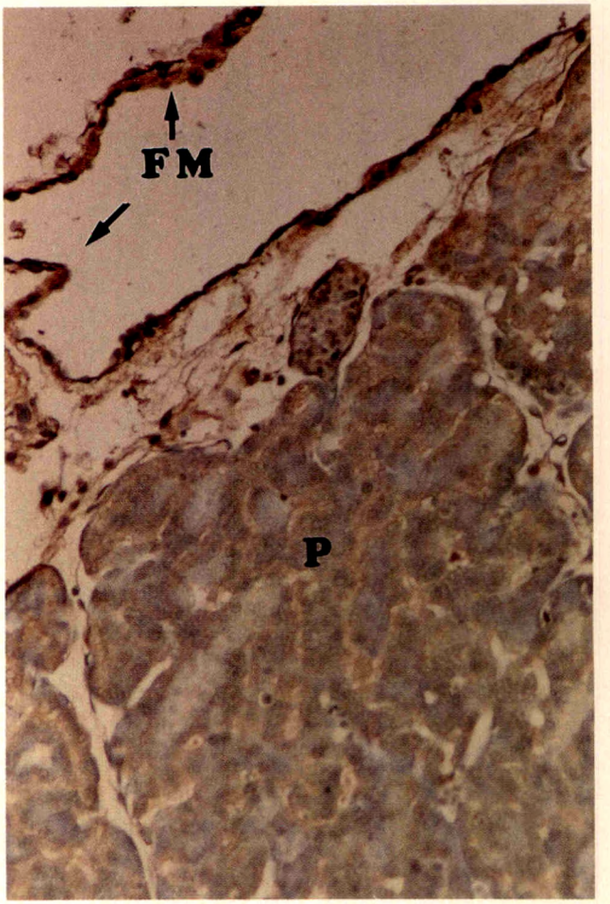

Fig. 3. Late implantation site (day 13) shows light to moderate GnRH immunostaining of true placenta (*P*). Fetal membranes (*FM*) stain more intensely than placenta. (× 145).

latory system. In addition, GnRH may play a role in a paracrine system related to local embryo-uterine interactions and nidation.

The physiologic function of this GnRH-like factor in the rabbit remains to be determined. Unlike in human beings, the mechanism by which the embryo maintains corpus luteum function is not clear. Browning et al.[15] failed to show any chorionic gonadotropin activity in rabbit placenta obtained on days 10, 18, and 26 of gestation. Gonadotropin-like activity was found to be greater in peripheral serum versus serum from the uterine vein. In addition, after removal of the conceptus at day 18, the corpus luteum of pregnant rabbits could be maintained with injections of steroid-free pituitary extracts or estrogen.[16] Although Nowak and Bahr[7] showed in vitro placental secretion of a GnRH-like factor in the rabbit, they found no difference in concentration between the uterine venous blood or peripheral blood. These studies therefore suggest that the GnRH-like substance secreted by the rabbit placenta acts locally and may be involved in early embryo-uterine signaling.[6, 7]

The immunostaining pattern of GnRH in the rabbit differs from that of the human being as well. Both the rabbit and human being[11] show intense GnRH immunoreactivity in cytotrophoblast. However, the staining pattern of the syncytiotrophoblast differs from that in human beings because immunoreactive GnRH is found only on the surface of the syncytiotrophoblast, whereas in rabbits there is no detectable GnRH immunoreactivity on the surface of the syncytiotrophoblast. In contrast, the GnRH immunostaining in the rabbit is found in the cytoplasm of the syncytial knobs. This difference could be because of the difference in species, the difference in the model studied (rabbit, in vivo perfusion; human being, curettage specimen) or to the difference in the physiologic role(s) for GnRH in human beings and rabbits. The length of gestation in the rabbit is 30 days and the distinction between cytotrophoblast and syncytiotrophoblast is lost after day 9 when the true placenta is formed. Whereas our study may cover a relatively wide gestational period, both our study and previous human studies cover the early part of gestation and should be comparable as far as interspecies differences allow. Finally, GnRH immunostaining was noted both before and after fusion of the trophoblast with the uterine epithelium. This suggests that the rabbit epithelium may contain a GnRH-like substance as in human beings.[17]

The GnRH immunostaining in obplacental giant cells is of interest. The exact origin of these cells is debated, but a recent study suggests that they are derived from the syncytiotrophoblast.[18] In addition, some researchers believe that the obplacental cells are luteotropic in the rabbit.[19] Immunoreactive GnRH was detected in the nucleus and cytoplasm of obplacental giant cells. The finding of immunoreactive GnRH on giant cells is consistent with the hypothesis[19] that they originate from

the syncytiotrophoblast and their luteotropic role in the rabbit. The significance of the nuclear staining is unknown. Further work in this area is needed.

In this study we show the presence of GnRH or a GnRH-like substance in the periimplantation and early postimplantation rabbit cytotrophoblast as the embryo prepares to adhere to and implant in the uterine epithelium. This finding lends further support for a proposed paracrine function for GnRH in both the human being and rabbit related to early embryo-uterine interaction and nidation.

Passive membrane properties and inward calcium current of human uterine smooth muscle cells

Roger C. Young, MD, PhD, Lea Herndon Smith, and Nels C. Anderson, Jr., PhD
Durham, North Carolina, and Charleston, South Carolina

Human myometrium was obtained at the time of cesarean delivery by means of excisional biopsy from the upper margin of the uterine incision through the lower uterine segment. Isolated smooth muscle cells were obtained by collagenase treatment. With the whole-cell patch clamp technique, voltage-clamp and current-clamp experiments were performed. Regenerative action potentials were seen in 3 mmol/L calcium bathing solution. Voltage-clamp experiments demonstrated the presence of transient inward currents and large outward currents. Inward currents were isolated with the use of tetraethylammonium ion as a blocking agent of outward current. In 3 mmol/L calcium inward current began at −60 mV and maximum inward current occurred at −40 mV. Maximum inward current density during the rising phase of the action potential was 1.0 μA/cm² in 3 mmol/L calcium and was unaffected by reduction of sodium concentration in the bathing solution. (Am J Obstet Gynecol 1991;164:1132-9.)

Key words: Human uterine smooth muscle, electrophysiology, voltage-activated calcium channel

Membrane excitability properties play an important role in the control of uterine contractility.[1] The rise in intracellular calcium that is necessary for smooth muscle contraction is a direct result of an action potential, which activates calcium ion flow across the surface membrane and possibly triggers release of intracellular calcium stores.[2-4]

Single-channel calcium conductances have recently been observed[5] in human uterine tissue with the use of the patch clamp technique.[6] The observation of two distinct conductance levels implied the existence of two types of calcium channels. We report here a characterization, including activation and inactivation properties, of the whole-cell calcium currents that were observed in human uterine smooth muscle cells freshly isolated from term pregnant women.

Material and methods

Preparation of cells. Cell isolation techniques were similar to those reported previously.[7] Small strips of human myometrium (0.5 cm × 0.5 cm × 2.0 cm) were excised from the upper margin of the uterine incision through the lower uterine segment at the time of cesarean delivery (Medical University of South Carolina Institutional Review Board Approval No. 3605). The tissue was transported and stored for up to 2 hours in 120 mmol/L sodium chloride, 5 mmol/L potassium chloride, 10 mmol/L HEPES (*N*-2-hydroxyethylpiperazine-*N*-2-ethansulfonic acid) buffer at pH 7.2. The serosa and endometrium were dissected free and discarded. The myometrium was minced into 1 mm cubes and washed in calcium-free, magnesium-free Hank's balanced salt solution (Sigma Chemical Co., St. Louis). The washed myometrial pieces were placed into an enzyme solution that was composed of 0.4% crude collagenase (type CLS 3, Worthington, Freehold, N.J.) in calcium-free magnesium-free Hank's balanced salt solution and agitated at 35° C for 20 minutes. The tissue was then placed into fresh enzyme solution under the same conditions for 30 minutes. The enzyme solution was then removed and the partially digested tissue was gently washed in 120 mmol/L sodium chloride, 5 mmol/L potassium chloride, 10 mmol/L HEPES buffer at pH 7.2. Free cells were liberated by repeated trituration of the tissue through a Pasteur pipette. These freshly dispersed cells are large, typically 150 to 300 μm in length and 10 to 15 μm in width. An aliquot of solution that contained free cells was then placed into the recording chamber. Most cells appeared to be elongated, with length-to-width ratios of approximately 20:1, and exhibited tapered ends. Cells with rounded ends or low length-to-width ratios were not considered appropriate for study.

Recording. The myometrial cells were allowed to settle and adhere to the glass bottom of the recording chamber. The recording chamber was then flooded

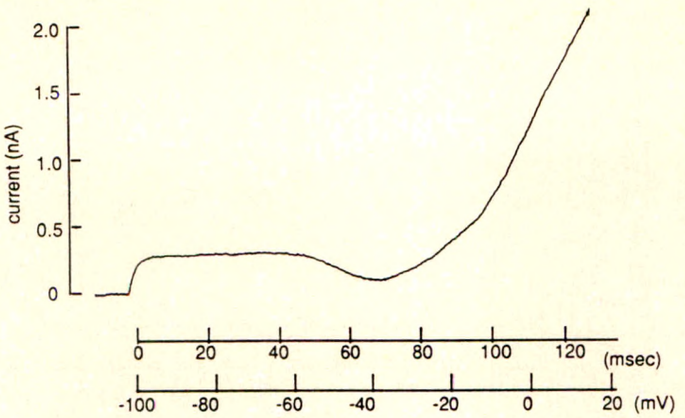

Fig. 1. Whole-cell voltage-clamp experiment. Current responses to voltage ramp. Bathing solution 1 (3 mmol/L calcium, 0 mmol/L TEA^+). Holding potential is −100 mV.

with an electrolyte bathing solution that was selected from the group of solutions in Table I. Cells were observed with a Zeiss Axiovert 35 inverted phase-contrast microscope (Carl Zeiss Inc., Thornwood, N.Y.).

Electrodes were pulled on a horizontal puller (Flaming-Brown, Sutter Instruments, San Rafael, Calif.) with borosilicate capillary tubes. Electrode resistances ranged from 4 to 7 MΩ when filled with electrolyte solution (solution 3, Table I).

Patch clamp recordings were performed with the Axopatch 1-B amplifier (Axon Instruments, Foster City, Calif.). A 1 GΩ feedback resistor was used, and data were filtered through a four-pole Bessel filter that was set at 2 kHz cutoff. After formation of a gigaohm seal between the patch pipette and the cell membrane, intracellular access was accomplished with moderate suction on the pipette at a holding potential of −60 mV under voltage-clamp conditions.

Data were digitized with the Axolab 1100 data acquisition system (Axon Instruments) and analyzed with the p-CLAMP software (Axon Instruments) on a Compaq 286 computer (Compac Computer Corp., Houston). All recordings were made at 20° to 25° C. Electrode capacitance and stray capacitance were electrically compensated; however, capacitive currents as a result of cell membrane capacitance were not compensated.

Voltage-clamp data were obtained by application of voltage-step or voltage-ramp commands from the holding potential to test potentials while the membrane current was monitored. By standard convention, positive ions that flow into the cell are defined as inward current and are represented by a downward deflection of current. The magnitude and time course of membrane currents were stable over time (up to 1 hour). An interval of at least 2 seconds between test pulses was necessary for the cell to reequilibrate and to avoid inactivation of membrane currents. For data reported here, 5 seconds was generally allowed as a convenient interval between test pulses.

Table I. Composition of solutions in millimoles per liter

	Bath		
	Solution 1	*Solution 2*	*Pipette—Solution 3*
Sodium chloride	120	60	5
Potassium chloride	5	5	120
Calcium chloride	3	3	0.1
TEA^+	0	60	—
HEPES	10	10	10
EGTA	–	–	1
pH	7.2	7.2	7.2

pH was adjusted to 7.2 ± 0.05 with sodium hydroxide for bathing solutions and with potassium hydroxide for the pipette solution. *EGTA*, Ethyleneglycol-*bis*-(β-aminoethylether)-N,N,N′,N′-tetraacetic acid.

Current-voltage curves were obtained by plotting observed currents against test potentials. Membrane currents were measured from the holding level, and unless specifically noted, were not corrected for leak. Data for inactivation curves were obtained with the double-pulse technique—a varying conditioning potential that was immediately followed by a constant test potential. These currents were corrected for leak before analysis. Curve-fitting of the inactivation curves was performed with Marquardt nonlinear regression with the aid of STATGRAPHICS software (STSC, Inc., Rockville, Md.). The equation fit was the Hodgkin-Huxley formulation[8] for inactivation: $I_{in}/I_{in}(max) = (1 + \exp[(V - V_{0.5})/k])^{-1}$ Fig. 1 demonstrates the use of a voltage ramp to determine membrane capacitance. At the beginning of the tracing the holding potential is −100 mV. At time 0, a voltage ramp of 1.07 V/sec is begun and applied for 140 msec. Be-

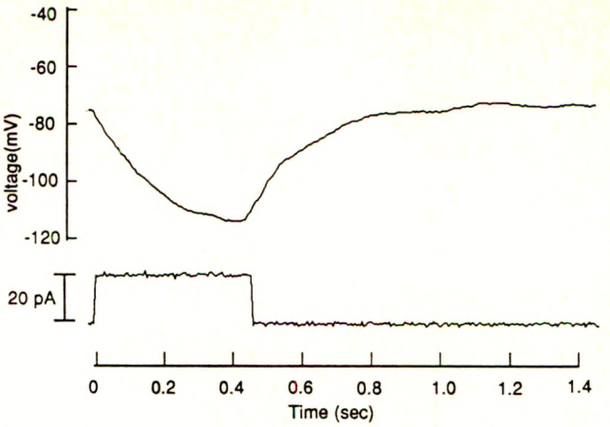

Fig. 2. Passive membrane potential response in the current clamp experiment. Bathing solution 1 (3 mmol/L calcium, 0 mmol/L TEA^+). A small hyperpolarizing current is applied to the cell to establish a resting membrane potential of −75 mV.

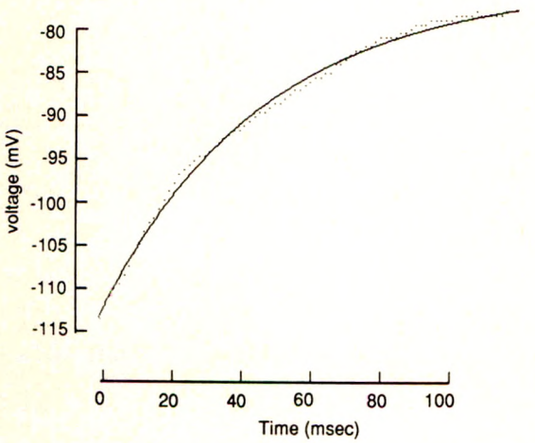

Fig. 3. Best-fit single exponential function *(solid line)* of voltage relaxation from data in Fig. 2.

tween −100 and −60 mV the response of the cell membrane is "passive" in that the electrical properties of the cell membrane can be described by a resistor (Rm) in parallel with a capacitor (Cm). The current response to the beginning of the voltage ramp is the charging of the membrane capacitance through the electrode resistance (Re) and is the current step that is seen at time 0 in Fig. 1. The capacitance is calculated from the height of the current step (Δi) through the relation $\Delta i = Cm \times \Delta V/\Delta t$, where $\Delta V/\Delta t$ is the ramp rate (1.07 V/sec). For the purpose of approximation of cell membrane surface area, we assume a unit membrane capacitance of 1.0 microfarads per square centimeter, which is found in other smooth muscle preparations,[9] and calculate the surface area from the capacitance measurement. Membrane resistances were calculated from the slope of the current response to the voltage ramp between −90 to −60 mV through the relation $Rm = \Delta E/\Delta i$. Unit membrane resistivities are membrane resistances that are corrected for cell surface area.

After the voltage-clamp experiments, current-clamp experiments were performed. Membrane potentials at zero applied current varied between −30 and −70 mV. Usually a small hyperpolarizing current was required to maintain the membrane potential in the −70 to −80 mV range.

Results

Passive membrane properties. Surface membrane capacitance and resistance measurements of freshly dispersed human uterine cells were obtained from voltage-ramp experiments (Fig. 1). The surface area of six cells varied between 8.0×10^{-5} and 2.9×10^{-4} cm^2. Measured membrane resistance values varied between 1 and 2 GΩ for those cells. Calculated resistivity varied between 0.8 and 2.25×10^5 Ω-cm^2.

Fig. 2 shows results from a current-clamp experiment and demonstrates membrane potential response to a hyperpolarizing current pulse. Fig. 3 shows the exponential fit of the relaxation phase of the membrane potential response that is shown in Fig. 2. This close fit is predicted by the equivalent circuit and indicates that the cell membrane properties are passive in this voltage range.

Membrane action potentials. Under conditions of 3mmol/L calcium, action potentials could be elicited with depolarizing current pulses or after a hyperpolarizing pulse (Fig. 4). The cell membrane voltage responses are pure expressions of membrane ion channel activity only under conditions in which the holding current is zero. Therefore analysis of action potentials was limited to those that were elicited by hyperpolarizing

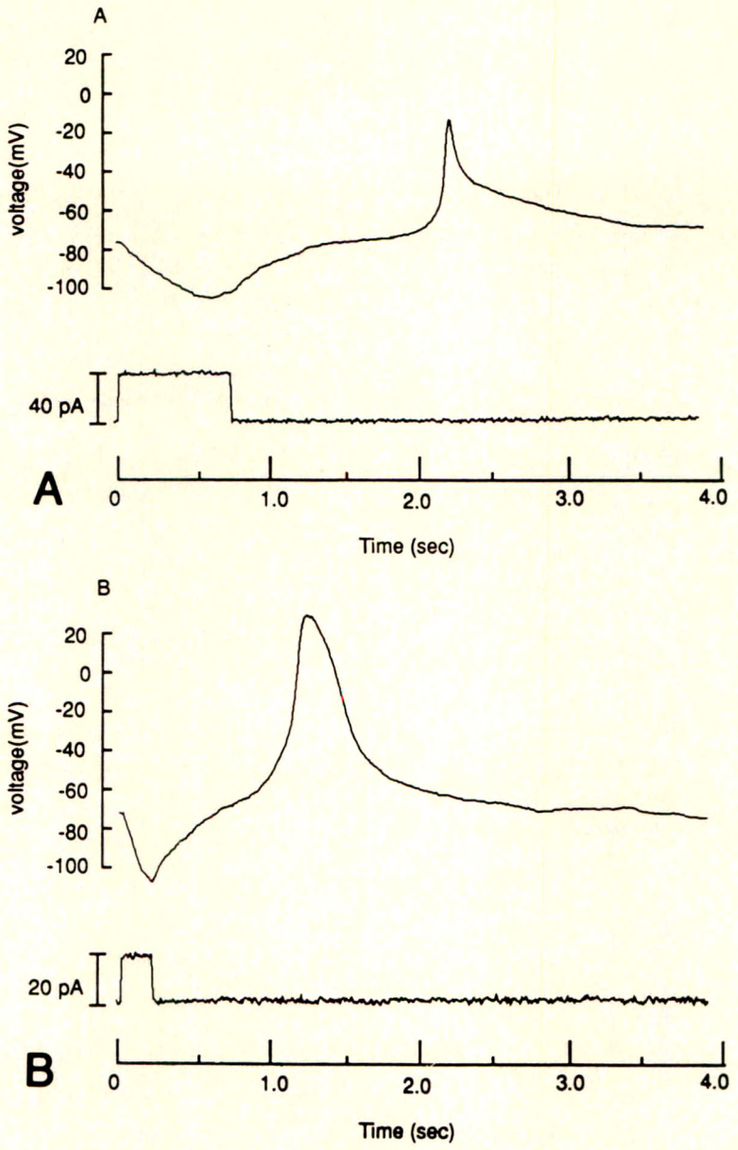

Fig. 4. Action potentials in the current-clamp experiment. **A,** Bathing solution 1 (3 mmol/L calcium, 0 mmol/L TEA^+). A 40 pA hyperpolarizing current pulse is applied for 750 msec. **B,** Same cell, with bathing solution changed to solution 2 (3 mmol/L calcium, 60 mmol/L TEA^+).

current pulses (anodal break excitation) or action potentials that occurred after depolarizing current pulses.

Without the use of blocking agents, the maximum depolarization that was observed in six cells was −17 mV (Fig. 4, *A*), and the maximal rate of voltage rise was 1.0 ± 0.2 V/sec for that cell. This voltage rise was the result of inward current that charged the membrane capacitance and is described by the relation $i = Cm \times dV/dt$. Thus, with the use of 1 $\mu F/cm^2$, the corresponding current density is 1.0 $\mu A/cm^2$.

With exchange of bathing solution so that TEA^+ (tetraethylammonium ion) (60 mmol/L) was substituted for sodium, the action potential duration lengthened, and the maximum depolarization increased to +20 mV (Fig. 4, *B*). However, the maximal rate of voltage rise for the action potential remained essentially unchanged at 0.79 V/sec. For three cells an average of 0.8 ± 0.2 V/sec was observed.

Action potential generation results from a complex interplay of ion channel opening and closing in response to membrane potential changes, calcium ion concentrations, and other parameters that affect membrane excitability properties. To help delineate the contribution of the calcium channel to the excitability properties of the membrane, whole-cell voltage clamp analysis was undertaken.

Voltage clamp analysis. In 3 mmol/L calcium under voltage-clamp conditions (Fig. 5), these cells demon-

strated complex currents. Outward currents in excess of 1 nA dominated inward currents, which made quantitative analysis of inward currents difficult. To isolate the inward calcium currents for study, outward currents were reduced by the use of TEA^+ (60 mmol/L) in the bathing solution.[10, 11]

The effect of TEA^+ (60 mmol/L) on human uterine myocytes is most easily observed in the voltage-ramp experiment (compare Fig. 6 with Fig. 1). Between −60 and −20 mV, similar inward currents occur in both the absence (Fig. 1) and the presence (Fig. 6) of TEA^+. At potentials above −20 mV, outward current rises rapidly, as shown in Fig. 1. This outward current is inhibited by TEA^+ (Fig. 6) and is consistent with blocking of potassium channels by TEA^+.

Current responses of the cell to stepped voltages with the TEA^+ (60 mmol/L) bathing solution are shown in Fig. 7. With the reduction in outward currents, inward currents are more easily observed. The resulting current-voltage curve (Fig. 8) of the peak inward current demonstrates that activation of the inward current begins at −60 mV and maximal inward current occurs at −40 mV. The value of 275 pA for maximal inward current corresponds to a current density of 1.1 $\mu A/cm^2$ (measured membrane capacitance was 240 picofarads for this cell). This is in good agreement with

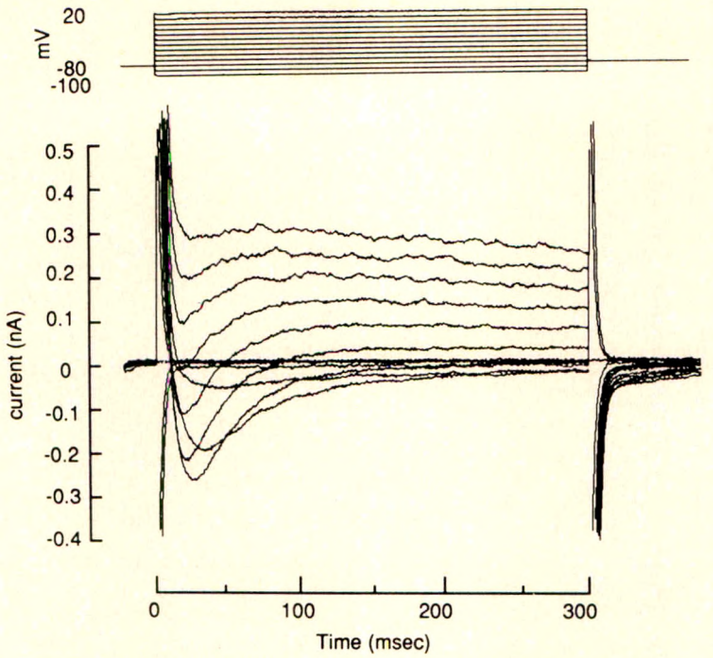

Fig. 7. Current responses to stepped voltages. Bathing solution 2 (3 mmol/L calcium, 60 mmol/L TEA^+). Holding potential and voltage protocol are identical to those in Fig. 5.

0.79 μA/cm², which was observed from the action potential of that cell.

Voltage inactivation of the inward current was performed by application of varying conditioning potentials for 250 msec followed immediately by a constant test pulse to −40 mV. A plot of the current responses to the test pulse versus conditioning potentials yields the Hodgkin-Huxley inactivation curve[8] (Fig. 9) with $V(1/2) = -54.9$ mV and $k = 4.5$ mV.

Comment

The experiments that are described here were performed on freshly dispersed pregnant human uterine smooth muscle cells. These cells readily formed gigaohm seals with patch pipettes and demonstrated reproducible passive and active properties under whole-cell voltage and current-clamp conditions. These experiments were performed on cells that were obtained from the lower uterine segment. Although the ideal tissue to study would be fundal tissue, those surgical specimens are difficult to obtain. Some elements of membrane excitability, such as channel density or receptor density, would be expected to vary depending on the site. However, the major features of membrane excitablity are the expression and regulation of ion-specific channels and are likely to be similar whether they originate in the fundus or the lower uterine segment.

Membrane resistivity. With the cell surface area as determined by capacitance measurement, membrane

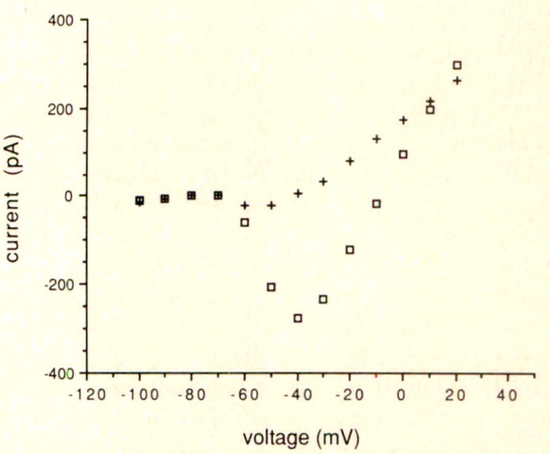

Fig. 8. Current-voltage relationship of data in Fig. 7 (3 mmol/L calcium, 60 mmol/L TEA^+). □, Peak inward current; +, current measured at 290 msec. The apparent reversal of inward current is artifact of decay of residual outward current.

resistivity in excess of 10^5 Ω-cm² in 3 mmol/L calcium was observed. The relatively large range among the six cells that are reported on here (from 0.8 to 2.25 × 10^5 Ω-cm²) is in part explained by difficulties in the determination of accurate measurements of very large resistances. Although pipette seal resistances were >5 GΩ, when 1 to 2 GΩ was measured, as much as a third of the current that was passed could be shunted by leakage of current from the electrode to the bath. Thus

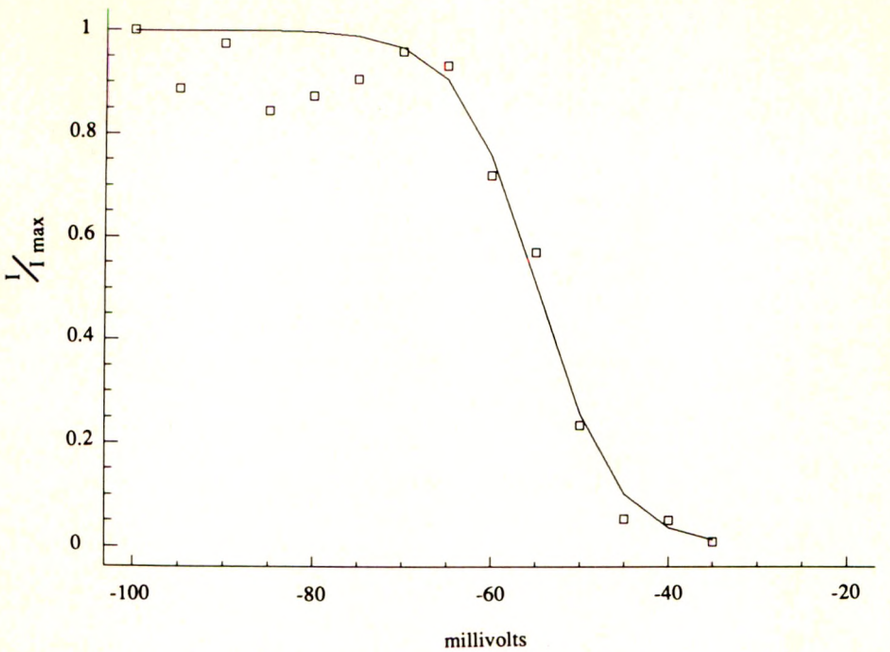

Fig. 9. Hodgkin-Huxley inactivation curve[8] of peak inward current. Data were obtained from same cell that was used to obtain data shown in Figs. 7 and 8. Best fit of data *(solid line)* yields $V_{1/2} = -54.5$ mV, K = 4.5 mV.

measured values of membrane resistivities should be interpreted as a lower limit. In addition, any significant cell damage during the isolation procedure would likely reduce measured membrane resistivity values.

These values are similar to those that have been reported for visceral[10, 12] and vascular[13, 14] smooth muscle cells. The importance of the unit membrane passive properties in relation to the active membrane properties, hormonal stimulation, site of biopsy, previous labor, or other clinical parameters awaits systematic study.

Inward current—the voltage-activated calcium channel. In agreement with many other smooth muscle systems, the inward currents that were observed in human myometrium are the expression of voltage-activated calcium channels.[1] The contribution of sodium currents[15] to the action potentials is probably not significant since replacement of half of the bathing solution sodium with TEA^+ increased rather than decreased the overshoot of the action potential (-17 to $+20$ mV). In addition, there was no significant change in the maximal rate of voltage rise of the action potential spike (1.0 vs 0.8 ± 0.2 V/sec). Further voltage-clamp studies in the 2 to 10 msec time frame will be required to determine whether sodium currents contribute to the action potential to any significant degree.

Evidence for two types of calcium channels was recently reported.[5] In this work, the voltage inactivation of the inward current (Fig. 8) was well fit by the Hodgkin-Huxley curve[8] with rapidly developing inactivation (k = 4.5 mV), which implies that the different types of calcium channels have similar, if not identical, inactivation characteristics.

In the cells that were studied in this experiment, there were only minor differences among the current-voltage relationships and the rate of decay of the inward current transients. Inward current was studied under ionic conditions that were as close to normal as possible. Specifically, a physiologic calcium concentration (3 mmol/L) was used to avoid artifactual changes of the current-voltage relationships that are noted in solutions with elevated calcium concentrations.[12]

Importance of the resting potential. The beginning of the inward current activation (-60 mV) is near the half-maximal inactivation (-54.9 mV). Thus this voltage range is crucial to the excitability of the cell membrane. The relatively short duration of the conditioning pulse (250 msec) in the inactivation protocol was chosen to ensure that inactivation of the calcium currents would occur on a time frame that was shorter than the time frame of slow-wave depolarization.[16] At resting membrane potentials that are more negative than -60 mV, no calcium ions flow into the cell, but calcium channels would be activated on slight depolarization. At resting potentials in which most of the calcium channels are inactivated (around -50 mV and more positive), no calcium ions flow into the cell and no action potentials would be generated regardless of further

depolarization. Thus a major controlling factor of the excitability of the membrane is the resting potential.

Propagation of the action potential through a syncytium. The ability of an intact uterus to undergo a coordinated contraction presumably requires propagation of the action potential from the fundus to the lower uterine segment. The propagation mechanism likely involves the action potential of one myocyte that causes depolarization of adjacent cells and leads to a spread of action potentials.[17] This would require myometrial cells that are at the leading edge of the action potential to be at a resting potential more negative than −60 mV; otherwise, propagation would cease. The presence of gap junctions[17] between adjacent cells allows for electrical communication and tends to equate the membrane potentials of the cells. With significant numbers of gap junctions, an electrical syncytium is established, within which all of cells are near the same resting membrane potential. Thus we believe that gap junctions not only aid in the transmission of the action potential from cell to cell but are required to establish membrane potentials along a path of propagation that is sufficiently negative to prevent calcium channel inactivation.

We thank Warren Smith for his assistance in the equivalent circuit analysis.

Intraabdominal sound levels during vibroacoustic stimulation

Ernest M. Graham, MD,[a] Aemil J.M. Peters,[a] Robert M. Abrams, PhD,[a, b]
Kenneth J. Gerhardt, PhD,[c] and David J. Burchfield, MD[b]
Gainesville, Florida

Vibroacoustic stimulation is widely used in the United States as a test for fetal well-being, yet little information is available on the adequacy of the electronic artificial larynx that is commonly used as the stimulator. To determine whether the intraabdominal sound pressure level was dependent on the static force applied to the electronic artificial larynx, we measured the sound pressure level at a position 20 cm from the surface of the anterior abdominal wall in nonpregnant ewes. The electronic artificial larynx was pressed against the surface with three levels of static force: mild, moderate, and strong. Between mild and strong static forces there was a trend toward a reduction in sound pressure level at the fundamental frequency (85 Hz) and the overtones (170 to 1600 Hz) ($p < 0.08$). To further examine the relationship between the static force of sound source against the abdomen and the intraabdominal sound pressure level, sine wave oscillations between 20 Hz and 4.0 kHz were produced with an industrial shaker. With a constant dynamic force (0.16 N) applied to the shaker across frequencies, the sound pressure level was greatest at lower frequencies (100 to 110 dB) and less at higher frequencies, above 1.0 kHz (60 to 80 dB). Consistent with the electronic artificial larynx experiments, strong application of the shaker resulted in greater transmission of sound than did mild application ($p < 0.02$). (Am J Obstet Gynecol 1991;164: 1140-4.)

Key words: Vibroacoustic stimulation test, intraabdominal sound pressure level

The fetal vibroacoustic test has become a popular method for testing antepartum and intrapartum fetal health.[1-3] Although the test is useful in the prediction of fetal well-being when the stimulus produces accelerations in fetal heart rate and increased heart rate variability, the test is much less accurate in the prediction of poor outcomes.[4-7] The electronic artificial larynx, the device that is most commonly used for fetal vibroacoustic testing, produces exceedingly high intrauterine sound pressure levels, as judged by recent experiments in sheep,[8] but only in an area directly under the skin site to which it is applied. Movement of the electronic artificial larynx by just 3 inches reduces the sound pressure level by as much as 20 dB.[8] Thus the position of the stimulator is one important factor in the determination of the level of the stimulus that is detected by the fetus and, by inference, the fetus's response. Difficulties in locating the fetal head, for example, could reduce the likelihood of a positive response even in a healthy fetus.

When the electronic artificial larynx is held in one hand and pressed with considerable force into the palm of the other, one notices a change in timbre of the sound of the vibrating diaphragm, which suggests an electromechanical overload of the diaphragm. If one presses too lightly, it reduces the strength of the mechanical coupling between the electronic artificial larynx and the palm with a resultant reduction in energy flow into the hand. This effect has been noted in studies of whole-body vibration.[9] Thus the static force (nonoscillating, continuous force expressed in centimeters of skin depression) with which the electronic artificial larynx is applied to the abdominal skin may be another variable of sound transmission and resultant intrauterine sound pressure level and fetal response.

To determine the effects that the strength of mechanical coupling between the vibrator and the abdomen has on the transmissibility of sound pressure as a function of frequency, we applied an electronic artificial larynx and a shaker actuator, which were driven with sine waves from 20 Hz to 4.0 kHz, to the abdominal skin at different static forces; we then recorded the resulting intraabdominal sound pressure levels.

Material and methods

Guidelines for the care and use of the animals, which were approved by the University of Florida, were followed. Six nonpregnant ewes were anesthetized intravenously with pentobarbital and then killed with intracardiac potassium chloride. The stomachs and intestines were removed through a midline incision, flushed to remove any gas-forming bacteria, and replaced with adequate saline solution to expand the abdominal cavities to their former dimensions. The incisions were

closed. A miniature hydrophone (model 8103, Bruel and Kjaer Instruments, Inc., Marlborough, Mass.), which was calibrated with a piston phone (model 4223, Bruel and Kjaer Instruments, Inc.), was placed intraabdominally through a stab wound in the flank of each ewe so that it was positioned 20 cm from the midline anterior wall.

Each ewe was placed on her side and vibration excitation was mechanically coupled horizontally against the midline skin by an electronic artificial larynx (Bell Telephone model 5-C, Western Electric, New York) or by a shaker (model PM 50, MB Electronics, Cleveland) controlled by a power amplifier (model 2250, MB Electronics). A schematic of the measurement setup with the shaker is shown in Fig. 1. An impedance head (model 8001, Bruel and Kjaer Instruments, Inc.) was placed in series with the actuator of the shaker. The dynamic force that was produced by the actuator was transduced by the impedance head, recorded as a root mean square voltage, and converted to newtons (kilograms × meters per square second). Dynamic force refers to that force that is produced by oscillation of a vibrator and calculated at the surface of the skin. Input force on the 1.32 cm^2 actuator head was held constant at 0.16 N for all test sinusoidal frequencies. The signals were produced by a frequency generator (model 3010, Synascan Corp., Chicago). The output of the force transducer was observed on an oscilloscope to verify the fidelity of the sine wave input to each animal.

Outputs from the hydrophone were conditioned with a charge amplifier (model 2635, Bruel and Kjaer Instruments, Inc.) and fed into a real-time frequency analyzer (model 2123, Bruel and Kjaer Instruments, Inc.). The analysis of the fundamental and harmonic contents of the signals throughout the frequency spectrum was achieved by measurement of constant percentage bandwidth filters. Spectra (1/24 octave; 1.4 Hz to 5.5 kHz) were averaged over 20 seconds, stored on a diskette, and plotted with a graphics plotter (model 2319, Bruel and Kjaer Instruments, Inc.). Spectral analysis results in a graphic display of the frequency and amplitude content of a particular stimulus.

Sound pressure at the fundamental frequency of the electronic artificial larynx and at all measurable overtones were recorded. In the shaker experiments we measured the sound pressure that was created by the sinusoidal input at frequencies of 20, 50, 75, 100, 150, 200, 300, 400, 500, 750 Hz and 1, 1.5, 2, 3 and 4 kHz.

The electronic artificial larynx and the shaker actuator were pressed against the animals' shaved skin to produce 1, 3, and 5 cm depressions. These depressions resulted in three degrees of static forces, which we termed: (A) mild, 1 cm depression of skin; (B) moderate, 3 cm depression; and (C) strong, 5 cm depression. The sound pressure level that was generated was compared across the frequencies by a two factor repeated measures analysis of variance, and the degree of vibrator force was used as a factor. The analysis was followed by a Tukey's multiple range test.

Results

Spectral analyses of signals from the intraabdominal hydrophone during stimulation with an electronic artificial larynx revealed a clear fundamental frequency of 85 Hz and many overtones (Fig. 2). From this figure it becomes apparent that the frequencies below approximately 1.0 kHz are in excess of the noise floor by 20 to 30 dB, whereas the levels at higher frequencies tend to be indistinguishable from the noise floor.

Results of the average amplitudes of the fundamental frequencies and overtones for the three conditions of static force are included in Fig. 3, along with the noise floor. The noise floor *(inverted triangles)* was determined by evaluation of the levels in 1/24-octave bands at frequencies immediately adjacent to the fundamental frequencies and overtones. As a group, sound pressure levels that were created by mild static force appeared to be lower than sound pressure levels that were produced by strong depression ($p < 0.08$) (Fig. 3). The disparity among sound pressure levels that were produced by varying electronic artificial larynx depression was greatest for frequencies above 1.0 kHz. With the electronic artificial larynx applied by mild force to the abdominal wall, the sound pressure levels above 1.0 kHz blended into the noise floor, whereas medium and strong static forces led to clear sound pressure levels that were above this background noise. Thus the greater the strength of application of the electronic

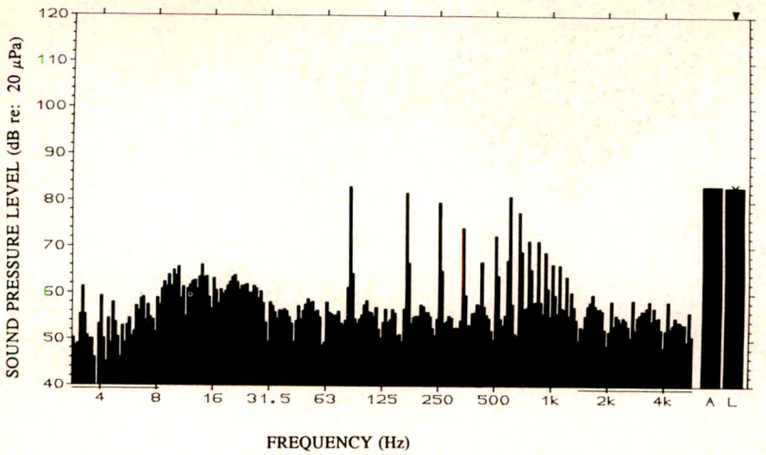

Fig. 2. 1/24-Octave band spectral display of intraabdominal sound pressure during stimulation with an electronic artificial larynx, which was applied with moderate static force.

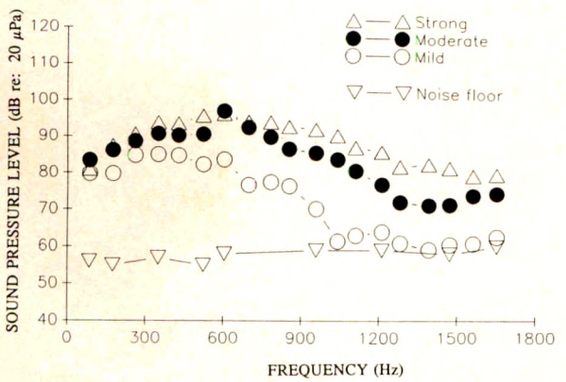

Fig. 3. Mean intraabdominal sound pressure ($n = 6$) recorded in 1/24-octave bands for the fundamental frequencies and overtones produced by an electronic artificial larynx applied to abdominal skin. Three static forces were used during stimulation with the electronic artificial larynx: ○, mild (1 cm depression of skin); ●, moderate (3 cm depression); and △, strong (5 cm depression). *Inverted triangles* represent average sound pressure in 1/24-octave bands that are immediately adjacent to fundamental frequencies and overtones and are representative of the noise floor for animals and recording equipment.

artificial larynx, the more likely it is that higher frequencies will penetrate to the hydrophone.

Similar results were found with the use of pure tones at selected frequencies that were generated by the shaker. Fig. 4 shows the two spectra that were produced in one animal with moderate static force of the shaker actuator against the skin and a constant dynamic force of 0.16 N. The 75 Hz pure tone (A) produced a signal over 100 dB, which is 40 dB above the noise floor, whereas a 750 Hz tone produced a signal of about 80 dB, which is only 20 dB above the noise floor. For the group as a whole, mild application of the shaker actuator led to lower sound pressure levels, as detected by the hydrophone than with strong application ($p < 0.02$) (Fig. 5).

Comment

The electronic artificial larynx is a fixed amplitude device that produces vibroacoustic energy over a wide spectral range.[8, 10] It was designed to aid aphonic patients in the generation of audible speech. Slight variations in force and position of the electronic artificial larynx against the throat modify the intensity and timbre of the sounds that are resonated by the nasopharyngeal and oral cavities. Coupling between vibrator and tissue is also important in the obstetric evaluation. With higher wall tensions, as might be expected in the tightly stretched abdomen of a slender pregnant woman at term, coupling would be expected to be optimal with less static force from the electronic artificial larynx.

At frequencies between 600 and 4000 Hz, the effect of skin depression and thus coupling between vibrators and abdominal contents was best observed. Interpretation of the results of the present experiments is hindered by the fact that the diminished distance between vibrator and hydrophone during strong depression (5 cm) of the vibrator may also have contributed to the higher sound pressure levels. As previously shown by Gerhardt et al.,[8] movement of an electronic artificial larynx laterally from its position immediately over a hydrophone leads to dramatic alterations in recorded intrauterine sound pressure level. In the current study at frequencies of 500 Hz and below, sound pressure level was less dependent on the depression-related coupling between electronic artificial larynx and the abdominal contents. Unless the electronic artificial

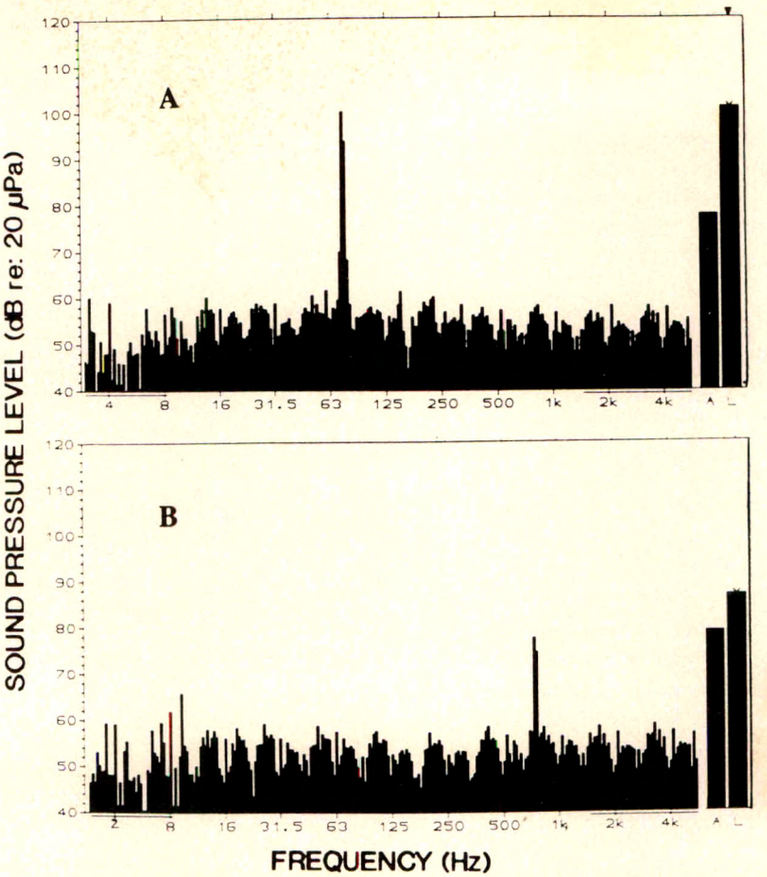

Fig. 4. 1/24-Octave band spectral displays of intraabdominal sound pressure during sinusoidal vibration of abdominal close-up surface at 75 Hz **(A)** and 750 Hz **(B).** Moderate static force was applied to the actuator.

larynx is pressed strongly against the abdomen, the sound pressure that is produced by vibration may not exceed the noise floor at frequencies of 1.0 kHz and above. Considering that one can expect an additional 10 to 15 dB of internal noise to be generated by the live, semirestrained animal,[11] it may be difficult to produce a high-frequency signal that can be detected by the fetal ear at some distance from the skin surface, even with strong depression of the electronic artificial larynx. Correct identification of the position of the fetal head before the vibroacoustic stimulation test is thus clearly required.

The noise floor of 50 to 60 dB (1/24-octave bands) represents the combined effects of room vibrations and sounds, tremors of the hand that is holding the electronic artificial larynx, and the hydrophone and charge amplifier noise floor. In comparison to the sound pressure level, which is created across many frequencies by the electronic artificial larynx, the signals that are produced by pure-tone sine waves can be made much more intense. By increasing the electrical power to the shaker,

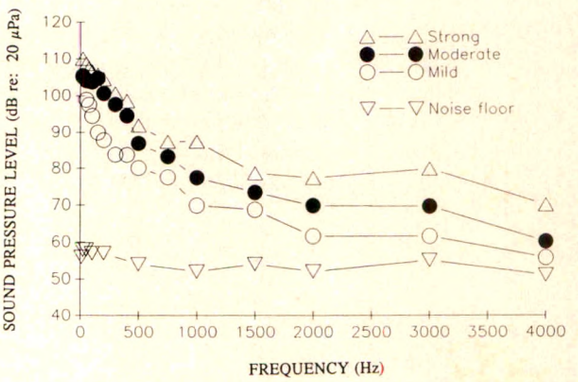

Fig. 5. Intraabdominal sound pressure recorded in 1/24-octave bands during application of a shaker with a constant dynamic force on the skin surface at several frequencies between 20 Hz and 4 kHz. Three static forces were used during sinusoidal stimulation: ○, mild (1 cm depression of skin); ●, moderate (3 cm depression); and △, strong (5 cm depression). *Inverted triangles* represent average sound pressure in 1/24-octave bands that are immediately adjacent to fundamental frequencies and overtones and are representative of the noise floor for animals and recording equipment.

much of the pressure can be focused in a single narrow band.

However, it is not known whether single pure tones are more efficacious than broader band signals in eliciting a fetal response. Gagnon et al.[12] reported an immediate and sustained increase in long-term fetal heart rate and the number of fetal heart rate accelerations when human fetuses were stimulated with a square wave at 100 Hz. An earlier study with a 2.0 kHz signal, which was produced by an earphone, showed increases in fetal movement after 1 minute of acoustic stimulus to the pregnant woman.[13] Although our study was not intended to evaluate fetal response, it is clear that low-frequency pure tones penetrate the abdomen with virtually no attenuation as a function of distance.

For both broad-spectrum sounds that are produced by an electronic artificial larynx and pure tones that are produced by a shaker, sounds at lower frequencies are transmitted unaffected by the static force that is applied to the abdomen, whereas signals at higher frequencies are absorbed. This is because the extent to which vibroacoustic energy penetrates tissue is dependent on frequency. Low frequencies with long wavelengths resemble acoustic compression waves and pass through tissue with little loss of energy. High frequencies with short wavelengths result in damped shear waves, and consequently, the energy is dissipated near the surface. The depth of penetration varies as the reciprocal of the square root of the frequency.[14]

Although the present experiments with dead, nonpregnant sheep might not totally simulate the conditions of supine, pregnant women at term, the results should alert obstetricians to two of the factors—mechanical coupling and vibration frequency—which must be considered in short-term diagnostic vibration exposures. Also of concern are these factors in exposures of longer duration of vibration, which are often encountered in the workplace. Any effect of vibration on the fetus is likely to be determined by a host of other factors including the mass and resonant frequencies of the abdominal segment, the thickness of the tissue that intervenes between maternal skin and fetus, the surface area of vibrating device, the vibration vector, and age of the fetus.

We thank Donald E. Wasserman for his many helpful comments and Jackie Combs for preparing the text.

Effect of progesterone on renin secretion in endometrial stromal, chorionic trophoblast, and mesenchymal monolayer cultures

Dinesh M. Shah, MD,[a, b] Kazumi Higuchi, MD, PhD,[c] Tadashi Inagami, PhD,[c] and Kevin G. Osteen, PhD[b]

San Antonio, Texas, and Nashville, Tennessee

Renin messenger ribonucleic acid expression has been shown in decidual tissue and endometrium, but weakly in chorion laeve, suggesting decidua as a primary source of uteroplacental renin. We proposed to confirm active renin secretion by endometrial stromal cells and examined the effect of progesterone-induced decidualization on secretion. Separate monolayer cultures of endometrial stroma, trophoblast, and mesenchymal cells were established and maintained for 10 to 15 days. Active renin concentration was measured with radioimmunoassay for angiotensin I generation and expressed as picograms per milliliter of angiotensin I generation per 10^5 cells. Active renin concentration was high in control secretory endometrial stromal cells (513 pg/ml) compared with trophoblast (none) and mesenchymal cell cultures (74 pg/ml). Marked decrease in active renin secretion occurred in control endometrial stromal cells (days 13 to 15, 86 pg/ml), whereas progesterone-induced decidualization sustained and increased secretion (days 13 to 15, 1017 pg/ml). This renin activity was quantitatively inhibited in culture fluid assays by specific human renal renin antibody in serial dilutions. Renin activity measurements before and after trypsin activation showed the majority of renin (91.15%) in the inactive form and a smaller fraction (8.85%) in the active form. Immunohistochemistry with the use of specific human renal renin antibody confirmed the presence of renin and its stimulation by progesterone in endometrial stromal cells. Progesterone had minimal effect on mesenchymal cells. These data confirmed endometrial stromal cells as a significant source of active renin and showed that progesterone induced a marked increase in this production. (Am J Obstet Gynecol 1991;164:1145-50.)

Key words: Renin in reproductive tissue cultures, hypertension in pregnancy

The renin-angiotensin system is recognized to have an important physiologic role in pregnancy. Brown et al.[1] found the plasma renin concentration in pregnant women to be greater than that in nonpregnant women. Although a significant part of this increased renin is present in its inactive form, plasma concentration of active renin is also increased in pregnancy.[2] It has been difficult to ascribe a role to renin in hypertensive disorders of pregnancy. Tapia et al.[3] found no significant difference in plasma renin activity and plasma renin substrate between normotensive and hypertensive pregnant women. Weir et al.[4] found plasma renin concentration, plasma renin substrate, angiogensin II, and aldosterone levels to be lower in the hypertensive group as compared with normal pregnancy.

The uteroplacental unit has been evaluated for its contribution to the renin-angiotensin system in pregnancy. Broughton-Pipkin et al.[5] found plasma renin concentration in the uterine vein to be no different from that in the antecubital vein in normotensive pregnancy, but in hypertensive subjects plasma renin concentration was significantly suppressed in the antecubital vein, as compared with the uterine venous level in the same subjects. The uteroplacental unit is also recognized to be a source of elevated circulating prorenin levels in normal pregnancy.[6] A role for the reproductive renin angiotensin system in the modulation of uteroplacental blood flow has been investigated. Gorden et al.[7] found the rabbit uterus to be a site of renin synthesis. Ferris et al.[8] have shown an increase in rabbit uterine renin secretion after experimentally induced uterine ischemia and suggested a role in the regulation of uterine blood flow.

Various tissues of the genital tract and fetoplacental unit have been shown to produce renin. Renin production by in vitro cultures of human chorion and uterine muscle was reported by Symonds et al.[9] Localization

of renin in trophoblasts in human chorion laeve at term pregnancy was shown by Poisner et al.[10] with immunohistochemistry. In an attempt to define the specific tissue responsible for reproductive renin, Shaw et al.[11] examined renin messenger ribonucleic acid expression in various reproductive tissues and suggested that decidua is a primary source of uteroplacental renin production. Recently, Symonds[12] reviewed the subject of renin-angiotensin system in pregnancy and defined four issues that need to be addressed when the role of renin in reproduction is considered: (1) the site of renin synthesis; (2) the nature of extrarenal renin; (3) the mechanism regulating renin release; and (4) the role of the system in the genital tract. The purpose of this investigation was to confirm endometrium as the primary tissue responsible for reproductive renin secretion in a tissue culture system, to examine the nature of this renin, and to examine the role of progesterone-induced decidualization in endometrial renin secretion.

Material and methods

Monolayer cultures

Endometrial specimens. Biopsy specimens were obtained in the secretory phase of the menstrual cycle in premenopausal women undergoing clinical evaluation. Isolation and culture of a highly purified population of stromal cells were established by a previously described method.[13] Briefly, biopsy specimens were placed in an ice-cold 1:1 mixture of Dulbecco's modified Eagle's medium/nutrient mixture F-12, dissected into small pieces, and washed by centrifugation. Enzymatic dissociation of tissue was accomplished in two distinct steps with 0.5% collagenase, 0.02% deoxyribonuclease, and 2% chicken serum. An intervening series of filtrations was done sequentialy through two monofilament nylon mesh membrane filters of 105 μm and 88 μm, respectively. The filtered stromal-enriched fraction was washed twice in Dulbecco's modified Eagle's medium/nutrient mixture F-12 and separated further from epithelial cell clumps by differential sedimentation at unit gravity. Last, the stromal cells from the second sedimentation were filtered through a 37-μm nylon mesh filter for final purification. After an initial 2-day incubation, the cells were cultured up to 15 days in serum-free Dulbecco's modified Eagle's medium/nutrient mixture F-12 with insulin, transferrin, sodium selenite media supplement in 24-well tissue culture plates at 37° C in an atmosphere of 95% air and 5% carbon dioxide. Paired samples of endometrial stroma were incubated with and without progesterone. Progesterone (50 ng/ml) was added to culture media for progesterone-induced decidualization.[14] Culture media were changed and collected at 3- to 4-day intervals and kept frozen at −20° C until radioimmunoassay for renin.

Chorionic cultures. Chorionic villus samples were obtained between 9 to 11 weeks' gestation for clinical indications. Larger pieces of villous material were separated from maternal decidua and blood clots with fine-point needles and forceps under sterile conditions. Villi were washed with 20% Chang medium and 80% Dulbecco's modified Eagle's medium mixed with 20% fetal calf serum. Enzymatic dissociation of trophoblast was carried out with 0.25% trypsin and mild agitation with a sterile pipette. Supernatant with trophoblast cells was removed from the mesenchymal sediment and centrifuged to remove trypsin. The cell pellet was plated in a flask that contained Dulbecco's modified Eagle's medium/nutrient mixture F-10 and Chang medium and incubated at 37° C in 5% carbon dioxide. Mesenchymal core sediment was treated with collagenase (50 mg in 7 ml of medium without fetal bovine serum), incubated for 2 hours, centrifuged, and then the cell pellet was plated in a flask in Dulbecco's modified Eagle's medium/nutrient mixture F-10 and 20% Chang medium and incubated at 37° C in 5% carbon dioxide. Culture fluids were changed and collected at intervals of every 3 to 5 days and kept frozen at −20° C until radioimmunoassay for renin.

Collection of these tissues was approved by the Committee for Protection of Human Subjects of Vanderbilt University Medical Center. Microscopic examination of these primary cultures showed that endometrial stromal cells were an elongated spindle shape with no obvious cell-to-cell processes. Trophoblast cells had epithelial-like morphology with multinucleated syncytia formation and mesenchymal cells were short with a spindle shape and small nuclei. Furthermore, it revealed that these samples contained more than 99% morphologically pure cell populations. Purity of endometrial stromal cell cultures has also been previously established.[13]

Radioimmunoassay for renin concentration. Renin concentration was measured in 50 μl of culture fluid incubated with sheep substrate for 60 minutes for angiotensin I generation. Radioimmunoassay of angiotensin I was peformed after a minimum 16-hour reaction time at 4° C with a previously described method.[15]

Trypsin activation of prorenin. Trypsin activation of inactive renin was carried out in 10 μl of sample with trypsin solution in the presence of bovine serum albumin over 30 minutes at room temperature. Reaction was halted with soybean trypsin inhibitor. Radioimmunoassay for angiotensin I was performed as described in this article to measure total renin. Trypsin-activable renin was calculated by subtracting active renin from total renin measurements.

Immunohistochemistry. After hydrogen peroxide and methanol treatment, washed, fixed, cultured

cells were treated with specific rabbit antihuman renal renin antibody (1:500 dilution). The specificity of this antibody had been characterized.[16] Horseradish peroxidase-streptavidin conjugate, combined with biotinylated secondary antibody (goat antirabbit immunoglobulin G) and nickel chloride–3,3′-diaminobenzidine was used as a visual marker. Counterstaining with eosin B was used to enhance contrast between renin-positive sites and background.

Statistics. Statistical comparison for control and progesterone-induced decidualized endometrial stromal cell renin produciton was made by the paired Student t test.

Results

Four specimens of secretory endometrial stromal cells, two of trophoblast, and two of mesenchymal core were studied for renin secretion. Table I and Fig. 1 show active renin concentration in endometrial stromal culture fluids, measured as angiotensin I generation over 60 minutes. Cell counts were performed by trypsinization, dilute (0.08%) trypan blue staining, and counting live cells in a hemocytometer chamber. Renin secretion is expressed as picograms per milliliter per 10^5 cells for paired specimens of control and progesterone-induced decidualized cells. There is a significantly high (1017 pg/ml vs 86 pg/ml, $p < 0.0001$, paired Student's t test) active renin concentration in culture fluid of progesterone-treated cells compared with control cells on days 13 to 15. Trophoblast culture fluids assayed simultaneously failed to reveal any renin activity. Mesenchymal cell culture fluids showed a small amount of active renin concentration (range, 25 to 114 pg/ml). This is shown in Table II and Fig. 2.

Renin specificity and trypsin activation. Culture fluid specimens obtained on 5 different days from two additional cultures of endometrium were studied for inhibition of renin activity by renin antibody and trypsin activation of renin. Quantitative inhibition of this renin activity was obtained with serial dilutions of specific human renal renin antibody (Fig. 3). Results of trypsin activation are presented in Table III. Approx-

imately 9% renin was in the active form and 91% in the inactive form.

Immunohistochemistry. Progesterone-induced decidualized endometrial stromal cells showed strongly positive staining by specific human renal renin antibody as compared with control cells, which showed only diffuse staining (Fig. 4). Mesenchymal cells showed minimal staining with a slight increase after progesterone treatment.

Comment

Renin activity has been noted to increase in pregnancy. Therefore the renin-angiotensin system has long been suspected to play a role in reproduction. It has been difficult to ascribe a role for renin in hypertension of pregnancy. Study of the renin-angiotensin system in uteroplacental blood has suggested it may play a role in uteroplacental blood flow regulation. The rabbit uterus has been shown to produce renin,[7] and increased renin secretion after experimentally induced ischemia in rabbits[8] suggests a role for renin in the regulation of uterine blood flow. In the chronically instrumented pregnant sheep, the effect of angiotensin II infusion[17] is reported to be related to the dose of infused angiotensin II. Increase in uterine blood flow occurred at low-dose infusion and a decrease was noted at high-dose angiotensin II infusion. This was explained[17] because increased perfusion pressure at low-doses offsets the effect of modest increases in uterine vascular resistance; whereas at high doses, a marked increase in uterine vascular resistance resulted in a decrease in uterine blood flow. This suggests that renin-angiotensin system may have a role in uterine vascular constriction and in the pathophysiology of uterine ischemia.

Renin production has been shown by a number of tissues of the human reproductive tract. Some of the previous studies have focused on identification of chorionic renin. In a study by Poisner et al.[10] renin was shown in chorionic membrane and in isolated cells of chorionic membrane by indirect immunofluorescence with rabbit antihuman renal renin antibody. It is conceivable that some of the immunofluorescence in the membrane may be in the mesenchymal cells. It is important that the method used for preparation of isolated cells with collagenase in that study may, at best, have provided a mixed preparation of trophoblast and mesenchymal cells. Our study with essentially pure cell

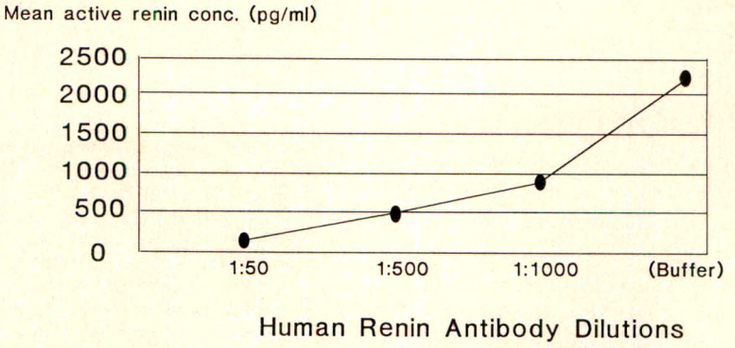

Fig. 3. Quantitative inhibition of renin activity by specific human renal renin antibody.

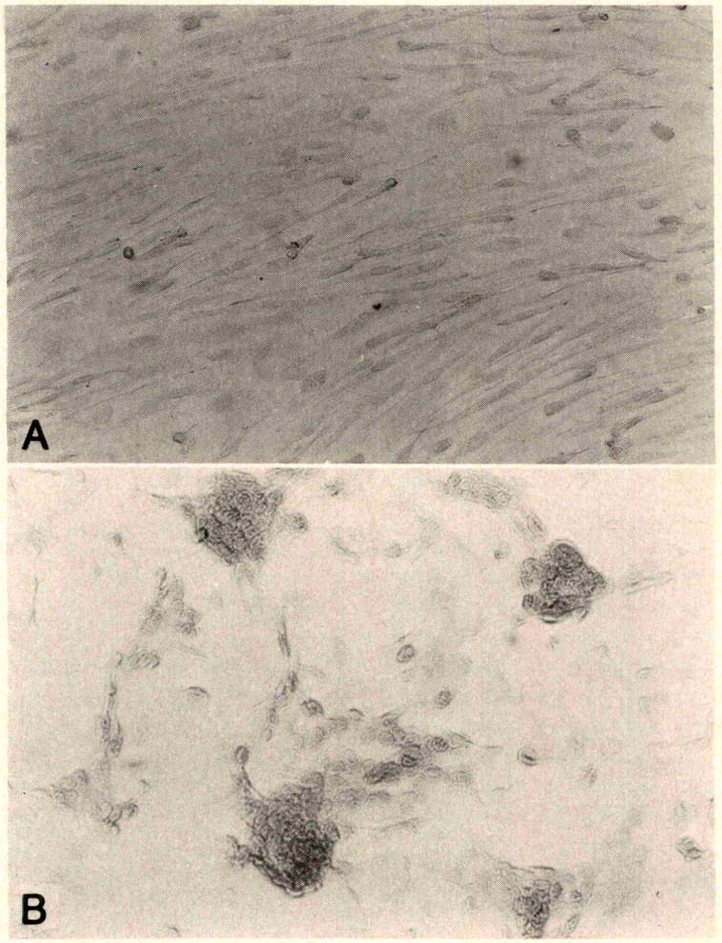

Fig. 4. Immunohistochemical evidence of renin in endometrial stromal cells in culture. **A,** Control cells; note spindle-shaped endometrial stromal cells with no staining by renin antibody. **B,** Progesterone-treated cells show morphologic features of in vitro decidualization. Note areas of enlarged cells with markedly dark staining in the cytoplasm by renin antibody.

populations failed to reveal any renin secretion by the trophoblast cell cultures and showed only a very small amount by the mesenchymal cell cultures under these experimental conditions. Thus our results are in disagreement with a previous study[10] that suggested the presence of chorionic renin of trophoblastic origin, but confirms secretion in small amounts by chorionic mesenchymal cells. Recent studies[11] of renin messenger ribonucleic acid have suggested endometrial cells, specifically decidua, to be the primary source of repro-

ductive renin. There is concern with regard to the nature of reproductive renin, inasmuch as a large portion of this tends to be inactive renin.[6]

Our experiments examined renin secretion in endometrial culture fluids specifically for active and trypsin-activable renin. We used a recently described method to obtain pure endometrial stromal cell cultures.[13] We experimentally induced decidualization with progesterone.[14] Significant renin secretion was found in endometrial stromal cells isolated from secretory endometrium. There was marked decrease (from 513 pg/ml to 86 pg/ml) in active renin secretion when cultures were maintained over a 15-day period. This decrease in renin secretion was prevented by progesterone treatment in paired samples and a marked increase (from 541 pg/ml to 1017 pg/ml) in active renin secretion was noted by days 13 to 15. This renin activity was quantitatively inhibited by specific human renal renin antibody. This suggests that renin-like material in the endometrial culture fluid is immunologically identical to purified human renal renin. This is important because other proteases (e.g., cathepsin D) have been shown to behave enzymologically similar to renin.[18] When renin acitivty was measured with and without trypsin activation, most of the renin (~91%) was present in the inactive form. This has also been the experience in other types of cells in culture.[19, 20] These culture fluid data were further substantiated by immunohistochemistry results, suggesting that endometrial renin secretion is influenced in paracrine fashion by progesterone. Because increased renin in peripheral blood has been noted in the secretory phase of the menstrual cycle[21, 22] and a significant increase in peripheral plasma renin concentration occurs in the first trimester of pregnancy,[2] our data further substantiate the concept of reproductive renin being under progesterone control. A significant aspect of our study is that a portion of this renin (~10%) is in the active form. This then may have a role in vasomotor modulation of uterine vasculature in pregnancy. Further studies are needed to establish this progesterone-induced renin secretion in experimental cultures and to evaluate its role in the regulation of uteroplacental blood flow.

We gratefully acknowledge the technical support of Laura Hobbs, BS, Mary Stevenson, MS, and Lynne Black, BS.

LETTERS TO THE EDITORS

A method for safer urinary incontinence surgery

To the Editors: I would like to share a technique that I have now used successfully for the past 3 months. This past summer, while I was teaching a resident to do a Burch urethropexy,[1] I realized the inherent danger that is involved in directing a needle toward the "unprotected" finger in the vagina. After some thought, I purchased a packet of metal sewing thimbles for the reasonable price of 65 cents. Our nurses autoclave these for me.

With the proper size thimble placed over the surgeon's gloved index finger, the stitches can be placed safely and comfortably. The middle finger is left "bare" to provide better tactile sensation when the surgeon palpates the urethra. I have also used this technique in Richardson repairs[2] and it worked well. A little practice may be necessary to get comfortable with the use of the thimble Surgeons can practice with a thimble, a needle holder, a needle and suture, and a surgery towel to simulate the vaginal tissue. Also, use of the thimble will probably improve the tissue purchase a surgeon takes. As an experiment, compare the size of the "bite" in the surgical towel taken with the thimble as opposed to that taken with the "unprotected" finger. Both the Burch urethropexy and the Richardson repair are excellent procedures, and I have often thought that the reason for the occasional failures is inadequate suture placement. Although I have not tried it, the thimble should also work nicely in Marshall-Marchetti-Krantz procedures.

I heard this week that Dr. David Richardson, who has contributed greatly to the field of urogynecology, has designed a device that serves a similar purpose. At present, the sewing thimble is more universally available and less expensive.

I may not be the first person to think of this and certainly would not want to take undeserved credit. However, after I talked to some of the experts in the field of urogynecology, I found that none had tried this method. I am presently accumulating data on my "thimble" patients, and thus far all of them have done well.

Today, all of us must treat each patient as a potential source of infection and take precautions. I am compelled to share this technique with my colleagues with the hope that it will protect them from needle sticks, improve their surgical results, and make teaching these procedures safer and easier.

John W. Gallaspy, MD

Fetal distress

To the Editors: We read with interest the article on fetal distress by Parer and Livingston (Parer JT, Livingston EG. What is fetal distress? AM J OBSTET GYNECOL 1990;162:1421-7). Their hypothesis that the onset of decompensation of the fetal physiologic responses to asphyxia is heralded by the occurrence of a decrease or loss of fetal heart rate (FHR) variability in the presence of stressed FHR patterns is an interesting one.

In our current quest for more objective indicators of clinically significant fetal asphyxia occurring during labor, we need to define clearly and evaluate prospectively those fetal physiologic functions that closely mirror the time course, the degree, and the duration of the asphyxial insult. Several fetal hemodynamic, biochemical, and electrophysiologic functions lend themselves to this purpose,[1] and fetal electrocardiogram (ECG) is one of them. Until recently, the wealth of potentially useful information conveyed by fetal ECG could not be tapped because of a variety of problems. With the arrival of newer generation of microprocessors and digital computer systems based on these microprocessors, the twin major hurdles of noisy fetal ECG signal and inability to handle and process voluminous digital data in real time have been overcome by the use of suitable software techniques.[2]

As a result of these developments in the field of digital electronics, it is now possible to obtain from the fetal ECG signal, besides FHR and its variability, information on time intervals (e.g., PR interval, QRS duration) and ST segment position continuously during labor. In a clinical study of fetal ECG with a minicomputer system equipped with time coherent averaging software routine, Murray[3] found that in the presence of a positive correlation between FHR and PR interval significant changes in the position of ST segment indicated increasing acidity of the fetal blood. He also reported that the on-line monitoring of the relationship between FHR and PR interval allowed the clinician to distinguish autonomically mediated FHR decelerations (with increased PR interval) from those that were metabolically mediated (i.e., a result of fetal hypoxia). Additional reports of the benefits of monitoring fetal ECG and the different methods used to monitor this signal may be found in a recent publication.[4]

Taken in conjunction with FHR variability, the additional information provided by the time intervals and the position of the ST segment of fetal ECG may allow us to monitor continuously the metabolic integrity of one of the three major organs preferentially favored by the fetal compensatory responses to asphyxia. The value of such an approach to the prevention of central

nervous system damage because of intrapartum asphyxia needs to be evaluated in prospective clinical studies.

Occupational vibration during pregnancy

To the Editors: Women are entering the workplace in increasing numbers[1] and are diversifying their choice of employment to include jobs in agriculture, construction, forestry, mining, transportation, and heavy industries in which vibration of all or parts of their bodies is significant. As a potential environmental hazard for a subset of working women who are pregnant, occupational vibration has received very little attention.

Although it is to be expected that prolonged exposure to vibration could result in increased fatigue and diminished performance,[2,3] certain conditions already present in pregnancy, such as abdominal and lower back pain, could be aggravated.[4] Low-frequency vibrations easily pass through the abdominal wall, uterine tissues, and fetal fluids[5] and could also have some adverse effects on the developing embryo or fetus.

Jobs in which the whole body is exposed to vibrations of 4 to 8 Hz are most risky, for it is in this range that the abdominal segment "resonates"[3] and is least likely to resist the oscillation forces that are imparted by machines on which women stand and sit or against which they lean.

As a group, obstetricians have done the most to publicize the fact that vibratory mechanical forces that are applied to the abdominal skin of pregnant women are easily transmitted to the fetus; in most cases, this results in fetal movements and cardioacceleration.[6,7] The fetal vibroacoustic stimulation test appears to be useful in confirming the presence of a healthy fetus that is destined for a healthy birth.[8] It is now time to broaden this clinical interest to include the effects of occupational vibration on pregnancy outcome. Unfortunately, the usual indices of outcome—premature birth, birth defects, Apgar and other neonatal scores—may not be sensitive enough to assess this type of exposure accurately.

Until a definite answer can be given to the question, "Does occupational vibration affect the course and outcome of pregnancy?" it is important to lobby for increased worker protection, worker education, and applied research in this emerging and growing area of concern for working pregnant women.

Group B streptococcal disease

To the Editors: We read the interesting article by Silver et al. (Silver HM, Gibbs RS, Gray BM, Dillon HC. Risk factors for perinatal group B streptococcal disease after amniotic fluid colonization. AM J OBSTET GYNECOL 1990;163:19-25) and we would like to add some data from our experience,[1] which could clear up some points.

In the first place, while studying at-risk patients (intraamniotic infection or rupture membranes >10 hours), the authors found that 81% of group B streptococcal vaginal carriers had group B streptococci in amniotic fluid during labor. They stated, "It is not possible to determine whether this is a usual occurrence or simply related to the method of patient selection." Because the reported value is similar to the 86% we found in our study of amniotic fluids 2 hours after rupture of the membranes in unselected intrapartum group B streptococcal carriers,[1] the majority of whom show no signs of intraamniotic infection, we think we may conclude that it is really a usual occurrence, even in patients without evidence of intraamniotic infection.

Similarly, the neonatal colonization rate reported when group B streptococci were cultured in amniotic fluid was 76%, compared with 69% in our work when they were cultured in amniotic fluid and/or in the vagina during delivery.

Finally, we would like to point out an interesting finding of the authors not mentioned in the discussion: 12% of patients had group B streptococci in amniotic fluid

but not in the vagina, a fact that is also consistent with the 19% reported by us[1] of the interpretation complex.

Reply

To the Editors: We would like to thank Drs. Matorras, Garcia-Perea, and Usandizaga for their interest in our article and for bringing their data to our attention. It is very intriguing that the findings in their group of unselected patients was so complementary to the findings in our high-risk group of patients. This underscores the need to further define the mechanism of transformation from asymptomatic colonization to overt infection with group B streptococcus if a successful prophylactic regimen is to be devised.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

HIGH-RISK OBSTETRICS

The Saudi Arabian Oil Company's (SAUDI ARAMCO) Medical Services Organization in Saudi Arabia is interviewing for experienced Obstetricians/Gynecologists with subspecialty in maternal fetal medicine to join an Obstetrical staff of 16.

With a patient population of approximately 200,000, Saudi Aramco's medical facilities provide comprehensive medical care to our employees and their dependents. The Dhahran Health Center, recently expanded to 483-beds, offers all major specialty services as well as sub-specialties and functions as a referral center. American Board Certification and two years' experience after residency required. Strong leadership qualities and experience in both a professional and administrative capacity are preferred.

As a Saudi Aramco employee, you will receive a competitive base compensation package, as well as an expatriate premium. Additional benefits include noncontributory group life insurance, company-matched savings, free medical care at Saudi Aramco's hospital and clinics, housing inside a company community, and extensive recreation facilities and activities. Your eligible children will be enrolled in company schools, comparable to U.S. private schools. There are up to 13 company holidays annually, and you will be eligible for 36 calendar days of vacation, with round trip airfares to the U.S. or Canada for you and your family.

Investigate these truly unique opportunities by calling **OUR 24 HOUR, 7 DAYS PER WEEK TOLL-FREE NUMBER LISTED BELOW.**

THE BREAST

A new quarterly international journal will be launched in Spring 1992

Announcement and call for papers

Chairman: Sir Patrick Forrest
Managing Editor: J Michael Dixon

Supported by an Editorial Committee and International Advisory Board drawn from experts world-wide

THE BREAST will cover the physiology of normal breast, the aetiology, biology, investigation, medical and surgical treatment and management of patients with benign and malignant breast disease. It will maintain a balance between basic sciences and clinical papers and will include results of animal research only when relevant to human issues.

High quality primary research papers will be published rapidly and all papers will be peer reviewed. Each issue of the journal will also carry one or more commissioned review articles, an occasional mini-symposium on controversial issues, annotated abstracts, case reports, correspondence, a calendar of forthcoming events and an up-to-date bibliography.

Papers are welcomed from authors in all specialties involved in breast research.

READERSHIP: Surgeons, Medical Oncologists, Epidemiologists, Biochemists, Pathologists, Radiologists, Endocrinologists and Radiotherapists.

ORIGINAL PAPERS should be sent to:
Mr J Michael Dixon, Senior Lecturer in Surgery,
University Department of Surgery, Royal Infirmary of Edinburgh,
Lauriston Place, Edinburgh EH3 9YW, UK

CURRENT PROBLEMS IN OBSTETRICS, GYNECOLOGY AND FERTILITY

Editor-in-Chief: Robert L. Barbieri, MD
State University of
New York at Stony Brook

Current Problems in Obstetrics, Gynecology and Fertility brings you the authoritative, practical information you need to stay current in your specialty and to provide the best possible care to patients.

- Each bimonthly issue provides in-depth, monograph-length coverage (40-60 pages) of a clinical topic of vital interest to practitioners today.
- Topics are selected for relevance to your daily practice: preconceptual counseling, infertility, endocrine problems, high-risk obstetrics, diagnosis and treatment of primary and secondary amenorrhea, pediatric and adolescent gynecology, and more.
- Authors are selected for their expertise; you'll benefit from their balanced perspective on the topic and their wealth of clinical experience.
- Each article is extensively referenced, saving you hours of library research.

Stay at the forefront of your specialty! Subscribe today by returning the order form or by calling our toll-free number.

Yes! Please begin my subscription to ***Current Problems in Obstetrics, Gynecology and Fertility*** (6 issues per year).

The one drug test a woman can't afford to fail.

Knowing the right answers to this test can mean the difference between life and death to a woman and her unborn child. Cut it out now and give copies to all your patients, even if you don't suspect a drug problem. Even if they are not pregnant. Because if your patients don't know the right answers, now's the time to talk with them and help them to understand.

Drugs and Pregnancy: Did you know?

1. Did you know that if you use cocaine while you're pregnant, you have a much greater chance of having a miscarriage? YES NO

2. Did you know that if you use cocaine, you can pass it on to your baby through your breast milk? YES NO

3. Did you know that if you use any illicit drug while you're pregnant, there's a greater chance that you will have a low-birthweight baby? YES NO

4. Did you know that low birthweight is associated with a greater risk of infant death and mental and physical handicaps? YES NO

5. Did you know that heroin use during pregnancy increases the likelihood of stillbirth and death among newborns? YES NO

6. Did you know that if you or any of your sexual partners ever used an illicit IV drug, you may be infected with the AIDS virus (HIV), and that you can pass that virus on to your unborn child? YES NO

7. Did you know that if you use cocaine, are addicted to heroin, or are methadone-dependent, your children will be at a greater risk for sudden infant death syndrome (SIDS)? YES NO

8. Did you know that if you use barbiturates during your pregnancy you can change your child's normal patterns of growth and behavior? Your child might also suffer withdrawal symptoms for months after birth, including high-pitched crying, irritability, and sleep disturbances. YES NO

9. Is your doctor aware of all the prescription and/or illicit drugs you may be taking? YES NO

Did you know that if you have a drug problem, there are many people and resources you can turn to for help? Just ask your doctor. YES NO

Cut along dotted line, copy, and distribute to patients as you see fit.

Limited Enrollment: **OBSTETRICS AND GYNECOLOGY REVIEW REGISTRATION**

Name _____

Address _____

City/State/Zip _____

Phone _____

For: ☐ June 3-8, 1991 – Chicago
☐ October 21-26, 1991 – Chicago
☐ December 2-7, 1991 – Chicago

☐ Check enclosed for $_____

☐ Please send **FREE SAMPLE**

Mail today to:

1094 Dawn Lane, Dept. 104
P.O. Box 2218
Terre Haute, IN 47802

*"Accommodations were comfortable...."**

COURSE AND LOCATION: This cours is a comprehensive review and update. Th fall course is more clinically oriented. Hom study questions are sent upon registratior The course includes lectures with syllabus a well as an opportunity to purchase an un limited number of optional extra one-on-on sessions with faculty to review your case list or do mock oral exams. Past participant recommend repeating the course for hal price immediately before exams. The cours will be at the Hilton Inn, Lisle, Illinois - $8 single; $110 double.

*"...and those little extras...."**

LOWEST AIR FARES: Please call toll free 1-800-548-8185 for group discounts.

*"...the most education for the money."**

FEES FOR 60 CATEGORY 1 HOURS:
- Practicing Gynecologists: $75
- Residents and Fellows: $50
- Repeating course within 2 years: $37
- Case-list reviews and mock oral exams (half hour sessions): $ 7
- Private mock oral exams: $10
- Optional extra day Dec. 8 (more questions, answers and pathology lab): $15
- **Add 10% within 10 days of the course.**
- Attendees not in course hotel add $20/day.
- Refunds, subject to $50 fee, will be mad until the seminar begins.
- A deposit of $50 will reserve your position.
- Most home study materials will be maile after half of the registration fee is received.

*"...home study material was extremely helpful."**

ACCREDITATION: Penn State is ac credited by the Accreditation Council fc Continuing Medical Education (ACCME) t sponsor continuing medical education fc physicians.
Penn State designates this continuing medi cal education activity for **60 credit hours** i **Category 1** of the Physican's Recognitio Award of the American Medical Associatior

*"...remarkably complete and pleasant."**

21- and 28-day regimens

ORTHO-NOVUM® 777 Tablets

norethindrone/ethinyl estradiol

Low incidence of androgenic side effects

Each white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet contains 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in 28-day regimen contains inert ingredients.

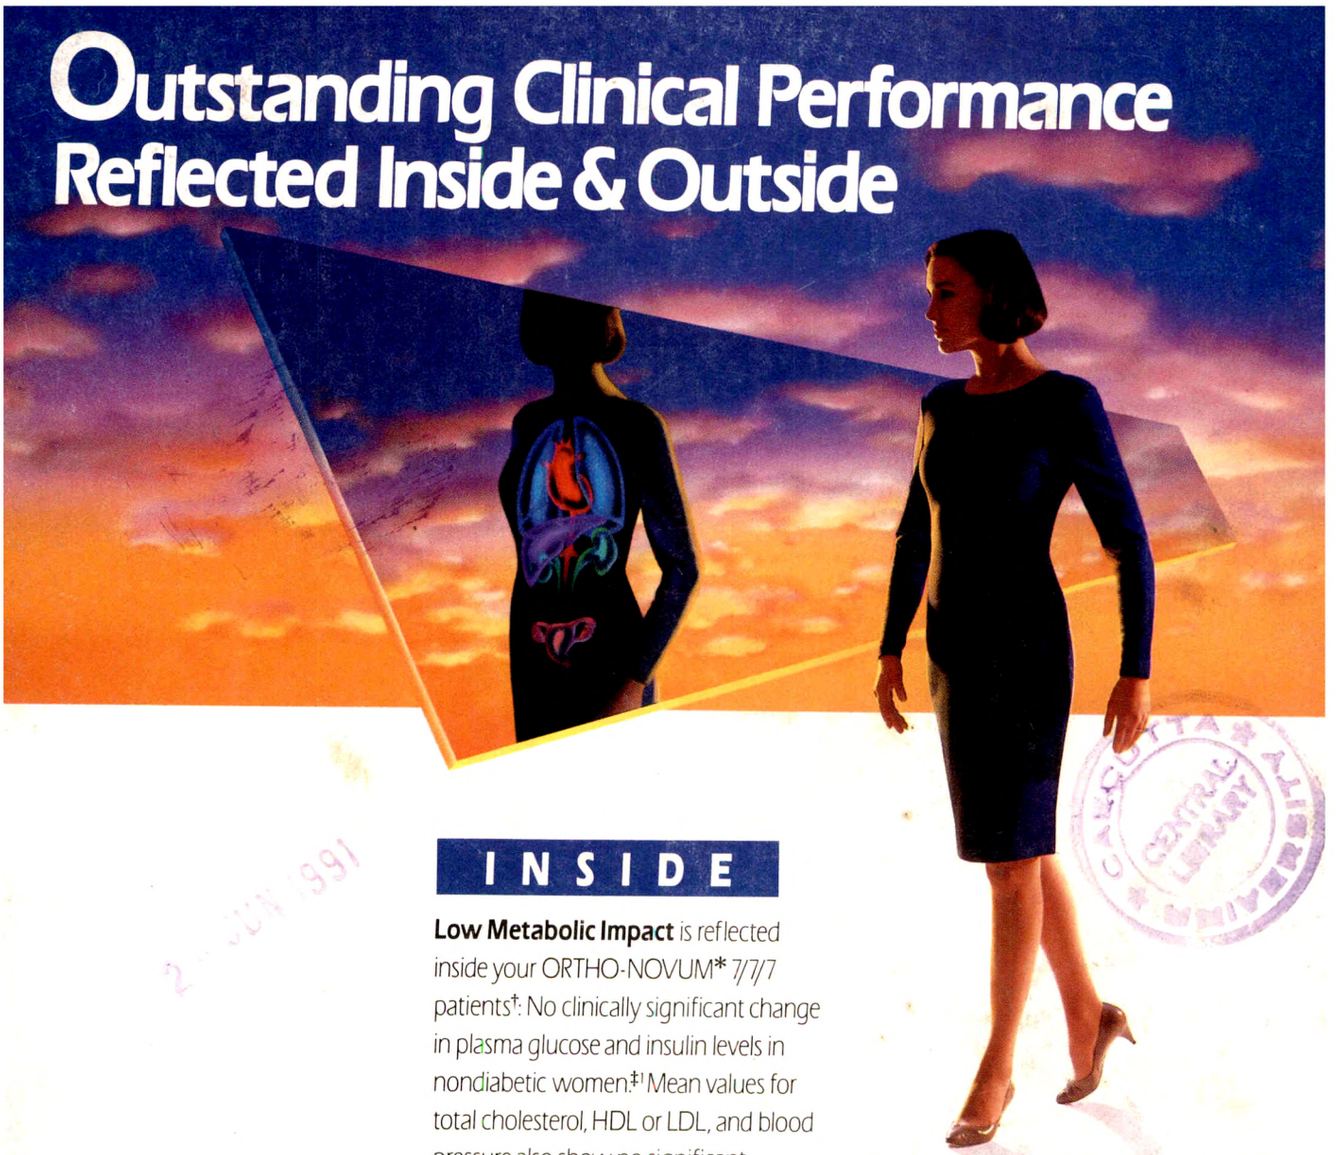
IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables and references. The physician should be thoroughly familiar with the complete prescribing information before prescribing the product.

INDICATIONS AND USAGE: PREVENTION OF PREGNANCY.

CONTRAINDICATIONS: Oral contraceptives should not be used in women who currently have the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Carcinoma of the endometrium or other known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Cholestatic jaundice of pregnancy or jaundice with prior pill use. 8. Hepatic adenomas or carcinomas. 9. Known or suspected pregnancy.

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.



The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia, and gallbladder disease, although the risk of serious morbidity or mortality is very small in healthy women without underlying risk factors. The risk of morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks. The information contained in this brief summary is principally based on studies carried out in patients who used oral contraceptives with higher formulations of estrogens and progestogens than those in common use today. The effect of long term use of the oral contraceptives with lower formulations of both estrogens and progestogens remains to be determined. Throughout this brief summary epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease, namely a *ratio* of the incidence of a disease among oral contraceptive users to that among nonusers. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and nonusers. The attributable risk does provide information about the actual occurrence of a disease in the population. For further information, the reader is referred to a text on epidemiological methods. 1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. a. Myocardial Infarction. An increased risk of myocardial infarction has been associated with oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity, and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be two to six. The risk is very low under the age of 30. Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women in their mid-thirties or older with smoking accounting for the majority of excess cases. Mortality rates associated with circulatory disease have been shown to increase substantially in smokers, especially in those 35 years of age and older among women who use oral contraceptives. Oral contraceptives may compound the effects of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see section 9 in WARNINGS). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors. b. Thromboembolism. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the relative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease associated with oral contraceptives is not related to length of use and disappears after pill use is stopped. A two- to four-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. The relative risk of venous thrombosis in women who have predisposing conditions is twice that of women without such medical conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and for two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and during and following prolonged immobilization. Since the immediate postpartum period is also associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than four weeks after delivery in women who elect not to breast feed. c. Cerebrovascular diseases. Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users, for both types of strokes, and smoking interacted to increase the risk of stroke. In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for nonsmokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk is also greater in older women. d. Dose-related risk of vascular disease from oral contraceptives. A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the activity of the progestogen used in the contraceptive. The activity and amount of both hormones should be considered in the choice of an oral contraceptive. Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing 0.035 mg or less of estrogen. e. Persistence of risk of vascular disease. There are two studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for five or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. However, both studies were performed with oral contraceptive formulations containing 50 micrograms or higher of estrogens. 2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE. One study gathered data from a variety of sources which have estimated the mortality rate associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. However, smokers 35 and older and non-smokers 40 and older who use oral contraceptives have a significant increase in mortality higher than those using other methods of birth control. These facts must be weighed in conjunction with failure rates for other methods and the risk associated with subsequent pregnancy. 3. CARCINOMA OF THE REPRODUCTIVE ORGANS. Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. While there are conflicting reports most studies suggest that use of oral contraceptives is not associated with an overall increase in the risk of developing breast cancer. Some studies have reported an increased relative risk of developing breast cancer, particularly at a younger age. This increased relative risk appears to be related to duration of use. Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. 4. HEPATIC NEOPLASIA. Benign hepatic adenomas are associated with oral contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use especially with oral contraceptives of higher dose. Rupture of benign, hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral contraceptive users. However, these cancers are rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users approaches less than one per million users. 5. OCULAR LESIONS. There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia, papilledema, or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately. 6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY. Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. The majority of recent studies also do not indicate a teratogenic effect, particularly in so far as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed two consecutive periods pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued until pregnancy is ruled out. 7. GALLBLADDER DISEASE. Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens. 8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. Oral contraceptives have been shown to cause a decrease in glucose tolerance in a significant percentage of users. This effect has been shown to be directly related to estrogen dose. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects prediabetic and diabetic women in particular should be carefully monitored while taking oral contraceptives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As discussed earlier (see WARNINGS 1a and 1d), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users. 9. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in women taking oral contraceptives, and this increase is more likely in older oral contraceptive users and with extended duration of use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing progestational activity. Women with a history of hypertension or hypertension-related diseases, or renal disease, should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension between former and never users. 10. HEADACHE. The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause. 11. BLEEDING IRREGULARITIES. Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent. 12. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. **PRECAUTIONS:** 1. PHYSICAL EXAMINATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMOTIONAL DISORDERS. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine and liver function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3, increased norepinephrine-induced platelet aggregability. b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radio-immunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINOGENESIS. See WARNINGS section. 10. PREGNANCY. Pregnancy Category X. See CONTRAINDICATIONS and WARNINGS sections. 11. NURSING MOTHERS. Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child. **INFORMATION FOR THE PATIENT: See Patient Package Insert. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS section). Thrombophlebitis and venous thrombosis with or without embolism. Arterial thromboembolism. Pulmonary embolism. Myocardial infarction. Cerebral hemorrhage. Cerebral thrombosis. Hypertension. Gallbladder disease. Hepatic adenomas or benign liver tumors. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea. Vomiting. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Amenorrhea. Temporary infertility after discontinuation of treatment. Edema. Melasma which may persist. Breast changes: tenderness, enlargement, secretion. Change in weight (increase or decrease). Change in cervical erosion and secretion. Diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: Pre-menstrual syndrome. Cataracts. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. Acne. Changes in libido. Colitis. **OVERDOSAGE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea and withdrawal bleeding may occur in females.

Revised 9/89

ORTHO

Outstanding Clinical Performance Reflected Inside & Outside

2 JUN 1991
CALCUTTA CENTRAL LIBRARY

INSIDE

Low Metabolic Impact is reflected inside your ORTHO-NOVUM* 7/7/7 patients†: No clinically significant change in plasma glucose and insulin levels in nondiabetic women.‡[1] Mean values for total cholesterol, HDL or LDL, and blood pressure also show no significant change.§

Excellent Cycle Control is another reflection of outstanding performance with ORTHO-NOVUM 7/7/7. You can expect low discontinuation rates due to breakthrough bleeding, spotting, and amenorrhea.

OUTSIDE

Low Incidence of Androgenic Side Effects—such as acne, oily skin, or hirsutism—is a visible reflection that your patients may notice; another is no clinically significant change in mean body weight. Inside and outside, the outstanding performance of ORTHO-NOVUM 7/7/7 is also an excellent reflection on you.

*Trademark

†Serious as well as minor side effects have been reported with the use of oral contraceptives. The physician should remain alert to the earliest manifestations of any symptoms of serious disease and discontinue oral contraceptive therapy when appropriate.

‡Oral contraceptives have been shown to cause a decrease in glucose tolerance in a significant percentage of users. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents.

§An increase in blood pressure has been reported in women taking oral contraceptives.

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

TRI-NORINYL®

Uniquely phased for all phases of a woman's reproductive life

ORAL CONTRACEPTIVE AGENTS: BRIEF SUMMARY

DESCRIPTION

TRI-NORINYL 21-DAY Tablets provide an oral contraceptive regimen of 7 blue tablets followed by 9 yellow-green tablets and 5 more blue tablets. Each blue tablet contains norethindrone 0.5 mg and ethinyl estradiol 0.035 mg and each yellow-green tablet contains norethindrone 1 mg and ethinyl estradiol 0.035 mg.

TRI-NORINYL 28-DAY Tablets provide a continuous oral contraceptive regimen of 7 blue tablets, 9 yellow-green tablets, 5 more blue tablets, and then 7 orange tablets. Each blue tablet contains norethindrone 0.5 mg and ethinyl estradiol 0.035 mg, each yellow-green tablet contains norethindrone 1 mg and ethinyl estradiol 0.035 mg, and each orange tablet contains inert ingredients.

INDICATIONS AND USAGE

Oral contraceptives are indicated for the prevention of pregnancy in women who elect to use these products as a method of contraception.

CONTRAINDICATIONS

Oral contraceptives should not be used in women who have the following conditions: Thrombophlebitis or thromboembolic disorders • A past history of deep vein thrombophlebitis or thromboembolic disorders • Cerebral vascular or coronary artery disease • Known or suspected carcinoma of the breast • Carcinoma of the endometrium, and known or suspected estrogen-dependent neoplasia • Undiagnosed abnormal genital bleeding • Cholestatic jaundice of pregnancy or jaundice with prior pill use • Hepatic adenomas, carcinomas or benign liver tumors • Known or suspected pregnancy

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia and gallbladder disease, although the risk of serious morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, hypercholesterolemia, obesity and diabetes.

Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

The information contained in this package insert is principally based on studies carried out in patients who used oral contraceptives with formulations containing 0.05 mg or higher of estrogen. The effects of long-term use with lower dose formulations of both estrogens and progestogens remain to be determined.

Throughout this labeling, epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease. Relative risk, the *ratio* of the incidence of a disease among oral contraceptive users to that among non-users, cannot be assessed directly from case control studies, but the odds ratio obtained is a measure of relative risk. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide not only a measure of the relative risk but a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and non-users. The attributable risk does provide information about the actual occurrence of a disease in the population.

1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS

a. Myocardial infarction

An increased risk of myocardial infarction has been attributed to oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be 2 to 6. The risk is very low under the age of 30. However, there is the possibility of a risk of cardiovascular disease even in very young women who take oral contraceptives.

Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women 35 or older, with smoking accounting for the majority of excess cases.

Mortality rates associated with circulatory disease have been shown to increase substantially in smokers over the age of 35 and non-smokers over the age of 40 among women who use oral contraceptives.

Oral contraceptives may compound the effects of well-known risk factors for coronary artery disease, such as hypertension, diabetes, hyperlipidemias, hypercholesterolemia, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and impair oral glucose tolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see **WARNINGS,** section 9). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors.

b. Thromboembolism

An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. One cohort study has shown the relative risk to be somewhat lower, about 3 for new cases (subjects with no past history of venous thrombosis or varicose veins) and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease due to oral contraceptives is not related to length of use and disappears after pill use is stopped.

A 2- to 6-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. If feasible, oral contraceptives should be discontinued at least 4 weeks prior to and for 2 weeks after elective surgery and during and following prolonged immobilization. Since the immediate postpartum period also is associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than 4 to 6 weeks after delivery in women who elect not to breast feed.

c. Cerebrovascular diseases

An increase in both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes) has been shown in users of oral contraceptives. In general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users for both types of strokes while smoking interacted to increase the risk for hemorrhagic strokes.

In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for non-smokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk also is greater in women 35 or older and among smokers.

d. Dose-related risk of vascular disease from oral contraceptives

A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with some progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the nature and absolute amount of progestogens used in the contraceptives. The amount of both hormones should be considered in the choice of an oral contraceptive.

Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing the lowest estrogen content that produces satisfactory results for the individual.

e. Persistence of risk of vascular disease

There are three studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for 5 or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. Subarachnoid hemorrhage also has a significantly increased relative risk after termination of use of oral contraceptives. However, these studies were performed with oral contraceptive formulations containing 0.05 mg or higher of estrogen.

2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE

One study gathered data from a variety of sources which have estimated the mortality rates associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. The observation of a possible increase in risk of mortality with age for oral contraceptive users is based on data gathered in the 1970's—but not reported in the U.S. until 1983. However, current clinical practice involves the use of lower estrogen dose formulations combined with careful restriction of oral contraceptive use to women who do not have the various risk factors listed in this labeling.

Because of these changes in practice and, also, because of some limited new data which suggest that the risk of cardiovascular disease with the use of oral contraceptives may now be less than previously observed, the Fertility and Maternal Health Drugs Advisory Committee was asked to review the topic in 1989. The Committee concluded that although cardiovascular disease risks may be increased with oral contraceptive use after age 40 in healthy non-smoking women (even with the newer low-dose formulations), there are greater potential health risks associated with pregnancy in older women and with the alternative surgical and medical procedures which may be necessary if such women do not have access to effective and acceptable means of contraception.

Therefore, the Committee recommended that the benefits of oral contraceptive use by healthy non-smoking women over 40 may outweigh the possible risks. Of course, older women, as all women who take oral contraceptives, should take the lowest possible dose formulation that is effective.

3. CARCINOMA OF THE BREAST AND REPRODUCTIVE ORGANS

Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. The evidence in the literature suggests that use of oral contraceptives is not associated with an increase in the risk of developing breast cancer, regardless of the age and parity of first use or with most of the marketed brands and doses. The Cancer and Steroid Hormone study also showed no latent effect on the risk of breast cancer for at least a decade following long-term use. A few studies have shown a slightly increased relative risk of developing breast cancer, although the methodology of these studies, which included differences in examination of users and non-users and differences in age at start of use, has been questioned. Some studies have reported an increased relative risk of developing breast cancer, particularly at a younger age. This increased relative risk appears to be related to duration of use.

Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors.

In spite of many studies of the relationship between oral contraceptive use and breast or cervical cancers, a cause and effect relationship has not been established.

4. HEPATIC NEOPLASIA

Benign hepatic adenomas are associated with oral contraceptive use although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases per 100,000 for users, a risk that increases after 4 or more years of use. Rupture of rare, benign, hepatic adenomas may cause death through intra-abdominal hemorrhage.

Studies in the United States and Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral contraceptive users. However, these cancers are extremely rare in the United States and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users is less than 1 per 1,000,000 users.

5. OCULAR LESIONS

There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately.

6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY

Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. More recent studies do not suggest a teratogenic effect, particularly insofar as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy.

The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion.

It is recommended that for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued if pregnancy is confirmed.

7. GALLBLADDER DISEASE

Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens.

8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS

Oral contraceptives have been shown to impair oral glucose tolerance. Oral contraceptives containing greater than 0.075 mg of estrogen cause glucose intolerance with impaired insulin secretion, while lower doses of estrogen may produce less glucose intolerance. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects, prediabetic and diabetic women should be carefully observed while taking oral contraceptives.

Some women may develop persistent hypertriglyceridemia while on the pill. As discussed earlier (see **WARNINGS**, sections 1a. and 1d.), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users.

9. ELEVATED BLOOD PRESSURE

An increase in blood pressure has been reported in women taking oral contraceptives. The incidence of risk also was reported to increase with continued use and among older women. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing concentrations of progestogens.

Women with a history of hypertension or hypertension-related diseases or renal disease should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives and there is no difference in the occurrence of hypertension among ever- and never-users.

10. HEADACHE

The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause.

11. BLEEDING IRREGULARITIES

Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first 3 months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding, as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was pre-existent.

PRECAUTIONS

1. PHYSICAL EXAMINATION AND FOLLOW-UP

A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology and relevant laboratory tests. In case of undiagnosed, persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care.

2. LIPID DISORDERS

Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult.

3. LIVER FUNCTION

If jaundice develops in any woman receiving oral contraceptives the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function.

4. FLUID RETENTION

Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention.

5. EMOTIONAL DISORDERS

Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree.

6. CONTACT LENSES

Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist.

7. DRUG INTERACTIONS

Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines.

8. INTERACTIONS WITH LABORATORY TESTS

Certain endocrine and liver function tests and blood components may be affected by oral contraceptives:

a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measurerd by protein-bound iodine (PBI), T4 by column or by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG. Free T4 concentration is unaltered.

c. Other binding proteins may be elevated in serum.

d. Sex steroid binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged.

e. Triglycerides may be increased.

f. Glucose tolerance may be decreased.

g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives.

9. CARCINOGENESIS

See **WARNINGS** section.

10. PREGNANCY

Pregnancy Category X. See **CONTRAINDICATIONS** and **WARNINGS** sections.

11. NURSING MOTHERS

Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child.

INFORMATION FOR THE PATIENT

See **PATIENT LABELING.**

ADVERSE REACTIONS

An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see **WARNINGS** section): Thrombophlebitis • Arterial thromboembolism • Pulmonary embolism • Myocardial infarction • Cerebral hemorrhage • Cerebral thrombosis • Hypertension • Gallbladder disease • Hepatic adenomas, carcinomas or benign liver tumors

There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis • Retinal thrombosis

The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea • Vomiting • Gastrointestinal symptoms (such as abdominal cramps and bloating) • Breakthrough bleeding • Spotting • Change in menstrual flow • Amenorrhea • Temporary infertility after discontinuation of treatment • Edema • Melasma which may persist • Breast changes: tenderness, enlargement, secretion • Change in weight (increase or decrease) • Change in cervical erosion and secretion • Diminution in lactation when given immediately postpartum • Cholestatic jaundice • Migraine • Rash (allergic) • Mental depression • Reduced tolerance to carbohydrates • Vaginal candidiasis • Change in corneal curvature (steepening) • Intolerance to contact lenses

The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: Pre-menstrual syndrome • Cataracts • Changes in appetite • Cystitis-like syndrome • Headache • Nervousness • Dizziness • Hirsutism • Loss of scalp hair • Erythema multiforme • Erythema nodosum • Hemorrhagic eruption • Vaginitis • Porphyria • Impaired renal function • Hemolytic uremic syndrome • Budd-Chiari syndrome • Acne • Changes in libido • Colitis

OVERDOSAGE

Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

NON-CONTRACEPTIVE HEALTH BENEFITS

The following non-contraceptive health benefits related to the use of oral contraceptives are supported by epidemiological studies which largely utilized oral contraceptive formulations containing estrogen doses exceeding 0.035 mg of ethinyl estradiol or 0.05 mg of mestranol.

Effects on menses: • Increased menstrual cycle regularity • Decreased blood loss and decreased incidence of iron deficiency anemia • Decreased incidence of dysmenorrhea

Effects related to inhibition of ovulation: • Decreased incidence of functional ovarian cysts • Decreased incidence of ectopic pregnancies

Effects from long-term use: • Decreased incidence of fibroadenomas and fibrocystic disease of the breast • Decreased incidence of acute pelvic inflammatory disease • Decreased incidence of endometrial cancer • Decreased incidence of ovarian cancer

SYNTEX

SYNTEX LABORATORIES, INC.
PALO ALTO, CA 94304

Nonsmoking, healthy woman in late-30s wishes to restart relationship with oral contraceptive. Low metabolic and hormonal impact preferred.

Active young female in late teens looking for lasting relationship with OC. Concerned about side effects of acne and bloating.

Career - oriented woman in mid-20s wants to find right OC. Wishes to avoid side effects such as weight gain, headache, and depression. Open to raising a family — but later.

A personalized approach to oral contraceptives.

Because Tri-Norinyl is uniquely phased for all phases of a woman's reproductive life, it's ideal for a wide range of patient types:

Older, nonsmoking patients restarting contraception: The only multiphasic with norethindrone that *lowers* progestin in late cycle to minimize overall hormonal and metabolic impact.

Career-oriented patients delaying childbearing: Reduced progestin helps minimize side effects such as weight gain, headache, and depression.

Younger patients just starting contraception: Low-impact progestin lowers risk of acne and bloating; mid-cycle increase enhances support when breakthrough bleeding is most likely to occur.

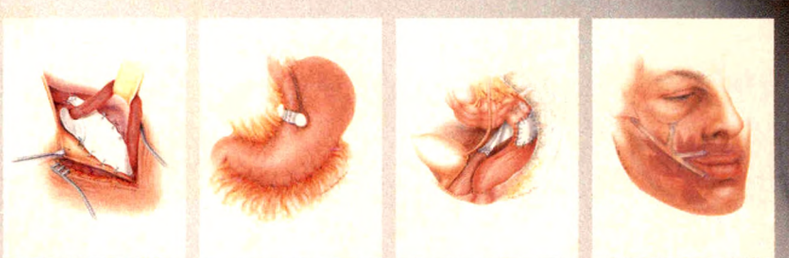
Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. Please see next page for brief summary of prescribing information. ©1990 Syntex Laboratories, Inc. 814-H2-201-90

GORE-TEX® SOFT TISSUE PATCH



In reconstructive surgery, a patient's own tissue is not always adequate. However, today surgeons do have alternatives. When a biomaterial is indicated, the GORE-TEX Soft Tissue Patch is the natural choice.

This remarkable sheet of GORE-TEX (expanded polytetrafluoroethylene) is engineered to provide improved performance in a wide range of applications. Since its introduction in 1982, the GORE-TEX Soft Tissue Patch has been used in more than 50,000 clinical cases worldwide.

The GORE-TEX Soft Tissue Patch combines high, balanced strength with softness and conformability. It is easy to shape and contour without fraying. Its microporous structure allows natural tissue ingrowth leading to potential treatability in the presence of infection. Next to delicate internal organs, the GORE-TEX Soft Tissue Patch has shown a significant reduction in adhesion formation and tissue erosion.

The exceptional versatility of the GORE-TEX Soft Tissue Patch makes it the natural choice in a wide range of applications.

- Abdominal Wall Reconstruction
- Hernia Repair
- Thoracic Wall Reconstruction
- Diaphragm Reconstruction
- Rectal and Vaginal Suspension
- Urethral Suspension
- Gastric Banding
- Facial Augmentation and Sling Procedures
- Related Pediatric Reconstructions

☐ Please send further information on the GORE-TEX Soft Tissue Patch.
☐ Please arrange for a free clinical sample.
☐ Please have your sales representative call for an appointment.

The Only GnRH* Agonist With The Dosing Distinction Of Intranasal Delivery

- Intranasal administration produces nafarelin serum levels comparable to I.V. dosing: In pharmacokinetic studies, SYNAREL was rapidly absorbed into systemic circulation following intranasal administration, with maximum serum concentrations achieved between 10 and 40 minutes.[1]

- B.I.D. controlled-dose intranasal administration suppresses serum estradiol to levels that result in outstanding clinical efficacy, while producing minimal impact on bone and a predictable hypoestrogenic profile.†
- Facilitates ease of patient management should allergic or other adverse events occur.
- Retreatment cannot be recommended since safety data for retreatment are not currently available.

1. Syntex document #829-222-A.

*Gonadotropin-releasing hormone analog.

†There is a small, largely reversible loss in bone density with 6-month treatment. Use of SYNAREL for longer than the recommended 6 months or in the presence of other known risk factors for decreased bone mineral content may cause additional bone loss.

Pregnancy should be ruled out before therapy with SYNAREL is initiated, and patients should be advised to use a non-hormonal method of contraception when taking SYNAREL.

Please see adjacent page for brief summary of prescribing information.

SYNAREL®

(NAFARELIN ACETATE)

NASAL SOLUTION, 2 MG/ML

Setting The Pace In Endometriosis Therapy

BRIEF SUMMARY

SYNAREL® Nasal Solution contains nafarelin acetate (2 mg/mL, expressed as nafarelin base), benzalkonium chloride, glacial acetic acid, sodium hydroxide or hydrochloric acid, sorbitol, and purified water.

INDICATIONS AND USAGE: For management of endometriosis. Experience is limited to women 18 years and older treated for 6 months.

CONTRAINDICATIONS: Hypersensitivity to GnRH, GnRH agonist analogs or any excipients in SYNAREL; undiagnosed abnormal vaginal bleeding; pregnancy or possibility of pregnancy while taking the drug because SYNAREL may cause fetal harm when administered to a pregnant woman. If SYNAREL is used during pregnancy or if the patient becomes pregnant while taking this drug, she should be apprised of the potential hazard to the fetus; use in women who are breast feeding.

WARNINGS: Safe use in pregnancy has not been established clinically. Before starting treatment pregnancy must be excluded.

When used regularly at the recommended dose, SYNAREL usually inhibits ovulation and stops menstruation. Contraception is not insured, particularly if patients miss successive doses. Therefore, patients should use nonhormonal contraception. Advise patients to see their physician if they believe they may be pregnant. If a patient becomes pregnant during treatment, discontinue the drug; apprise patient of the potential risk to the fetus.

PRECAUTIONS Information for Patients: 1. Since menstruation should stop with SYNAREL, the patient should notify her physician if regular menstruation persists. Patients missing successive doses may experience breakthrough bleeding.

2. Patients should not use SYNAREL if pregnant, breast feeding, have undiagnosed abnormal vaginal bleeding, or are allergic to any of its ingredients.

3. Safe use in pregnancy has not been established. Therefore, a nonhormonal method of contraception should be used during treatment. If a patient becomes pregnant during treatment, she should discontinue the drug and consult her physician.

4. Adverse events occurring most frequently in clinical studies are associated with hypoestrogenism. Nasal irritation occurred in about 10% of patients.

5. Induced hypoestrogenic state results in a small loss in bone density over a 6-month treatment course. Some of this loss may not be reversible. During one six-month treatment period, this should not be important. In patients with major risk factors for decreased bone mineral content, i.e., chronic alcohol and/or tobacco use, strong family history of osteoporosis, or chronic use of drugs that can reduce bone mass such as anticonvulsants or corticosteroids, SYNAREL may pose additional risk. In these patients risks and benefits must be weighed carefully. Repeated courses of treatment with GnRH analogs are not advisable in patients with major risk factors for loss of bone mineral content.

6. Patients with intercurrent rhinitis should consult their physician for use of a topical nasal decongestant. If a topical nasal decongestant is required during treatment, it must be used at least 30 minutes after SYNAREL dosing to decrease the possibility of reducing drug absorption.

7. Retreatment cannot be recommended since safety data beyond 6 months are not available.

Drug Interactions: No pharmacokinetic-based drug-drug interaction studies have been conducted. Nafarelin acetate is a peptide primarily degraded by peptidase and not by cytochrome P-450 enzymes, and is only about 80% bound to plasma proteins at 4°C; therefore drug interactions would not be expected to occur.

Drug/Laboratory Test Interactions: SYNAREL in therapeutic doses suppresses the pituitary-gonadal system. Normal function is usually restored 4-8 weeks after treatment is discontinued. Therefore, diagnostic tests of pituitary gonadotropic and gonadal functions during treatment and up to 4-8 weeks after discontinuation of SYNAREL may be misleading.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Carcinogenicity studies were conducted in rats and mice at intramuscular doses up to 110 times and 560 times the maximum recommended human intranasal dose, respectively. These multiples of the human dose are based on the relative bioavailability of the drug by the two routes of administration. As with other GnRH agonists, nafarelin acetate given to laboratory rodents at high doses for prolonged periods induced hyperplasia and/or neoplasia of endocrine organs. At 24 months, there was an increase in the incidence of pituitary tumors (adenoma/carcinoma) in high-dose female rats and a dose-related increase in male rats. There was an increase in pancreatic islet cell adenomas in both sexes, and in benign testicular and ovarian tumors in the treated groups. There was a dose-related increase in benign adrenal medullary tumors in treated female rats. In mice, there was a dose-related increase in Harderian gland tumors in males and an increase in pituitary adenomas in high-dose females. No metastases of these tumors were observed. It is known that tumorigenicity in rodents is particularly sensitive to hormonal stimulation.

Mutagenicity studies using bacterial, yeast, and mammalian systems provided no evidence of mutagenic potential.

Reproduction studies in male and female rats have shown full reversibility of fertility suppression when treatment was discontinued after continuous administration for up to 6 months.

Pregnancy, Teratogenic Effects: *Pregnancy Category X.* Intramuscular SYNAREL was administered to rats throughout gestation at about 0.5, 2, and 7 times the maximum recommended human intranasal dose based on the relative bioavailability by the two routes of administration. An increase in major fetal abnormalities was seen in 4/80 fetuses at the highest dose. A similar study at the same doses in rats and studies in mice and rabbits at doses up to 600 μg/kg/day and 0.18 μg/kg/day, respectively, failed to demonstrate an increase in fetal abnormalities after administration throughout gestation. In rats and rabbits, there was a dose-related increase in fetal mortality and a decrease in fetal weight with the highest dose.

Nursing Mothers: It is not known whether SYNAREL is excreted in human milk. Because many drugs are excreted in human milk, and because the effects of SYNAREL on lactation and/or the breastfed child have not been determined, SYNAREL should not be used by nursing mothers.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: The most frequently reported adverse reactions were those related to hypoestrogenism. In controlled studies comparing SYNAREL (400 μg/day) and danazol (600 or 800 mg/day), the following adverse reactions were most frequently reported and thought to be drug-related.

Hypoestrogenic: hot flashes (SYNAREL 90%, danazol 69%), decreased libido (22%, 7%), vaginal dryness (19%, 7%), headaches (19%, 21%), emotional lability (15%, 18%), insomnia (8%, 4%); **Androgenic:** acne (13%, 20%), myalgia (10%, 23%), reduced breast size (10%, 16%), edema (8%, 23%), seborrhea (8%, 17%), weight gain (8%, 28%), hirsutism (2%, 6%), increased libido (1%, 6%); **Local:** nasal irritation (10%, 3%); **Miscellaneous:** depression (2%, 5%), weight loss (1%, 3%).

Less than 1% of patients experienced paresthesia, palpitations, chloasma, maculopapular rash, eye pain, urticaria, asthenia, lactation, breast engorgement, and arthralgia. In clinical trials, immediate hypersensitivity thought to be possibly or probably related to nafarelin occurred in 3 (0.2%) of 1509 healthy subjects or patients.

Changes in Bone Density: After 6 months' treatment vertebral trabecular bone density and total vertebral bone mass, measured by quantitative computed tomography (QCT), decreased by an average of 8.7% and 4.3%, respectively, compared to pretreatment levels. There was partial recovery of bone density post-treatment; the average trabecular bone density and total bone mass were 4.9% and 3.3% less than pretreatment levels, respectively. Total vertebral bone mass, measured by dual photon absorptiometry (DPA), decreased by a mean of 5.9% at end of treatment. Mean total vertebral mass, re-examined by DPA 6 months post-treatment, was 1.4% below pretreatment levels. There was little, if any, decrease in the mineral content in compact bone of the distal radius and second metacarpal. Use for longer than the recommended 6 months or in presence of other known risk factors for decreased bone mineral content may cause additional bone loss.

Changes in Laboratory Values: *Plasma enzymes.* During clinical trials SGOT and SGPT levels were more than twice the upper limit of normal in only one patient each. There was no other evidence of abnormal liver function and levels returned to normal after treatment was stopped.

Lipids. At enrollment and at end of treatment, 9% of patients on SYNAREL 400 μg/day and 2% on danazol had total cholesterol values above 250 mg/dL.

Of those with pretreatment cholesterol values below 250 mg/dL, 6% on SYNAREL and 18% on danazol had post-treatment values above 250 mg/dL.

Mean (±SEM) pretreatment values for total cholesterol from all patients were 191.8 (4.3) mg/dL in the SYNAREL group and 193.1 (4.6) mg/dL in the danazol group. At the end of treatment, mean values from all patients were 204.5 (4.8) mg/dL in the SYNAREL group and 207.7 (5.1) mg/dL in the danazol group. These increases from pretreatment values were significant ($p < 0.05$) in both groups.

Triglycerides were increased above the upper limit of 150 mg/dL in 12% of the patients on SYNAREL and in 7% of the patients on danazol.

At the end of treatment, no patients on SYNAREL had abnormally low HDL cholesterol fractions (< 30 mg/dL) compared with 43% of patients on danazol. No patients on SYNAREL had abnormally high LDL cholesterol fractions (> 190 mg/dL) compared with 15% of those on danazol. There was no increase in the LDL/HDL ratio in patients on SYNAREL, but approximately a 2-fold increase in the LDL/HDL ratio in patients on danazol.

Other changes. In comparative studies, the following changes were seen in approximately 10% to 15% of patients. SYNAREL was associated with elevations of plasma phosphorous and eosinophil counts, and decreases in serum calcium and WBC counts. Danazol therapy was associated with an increase of hematocrit and WBC.

OVERDOSAGE: At present there is no clinical evidence of adverse effects following overdosage of GnRH analogs.

CURRENT PROBLEMS IN OBSTETRICS, GYNECOLOGY AND FERTILITY

Editor-in-Chief: Robert L. Barbieri, MD
State University of
New York at Stony Brook

Current Problems in Obstetrics, Gynecology and Fertility brings you the authoritative, practical information you need to stay current in your specialty and to provide the best possible care to patients.

- Each bimonthly issue provides in-depth, monograph-length coverage (40-60 pages) of a clinical topic of vital interest to practitioners today.
- Topics are selected for relevance to your daily practice: preconceptual counseling, infertility, endocrine problems, high-risk obstetrics, diagnosis and treatment of primary and secondary amenorrhea, pediatric and adolescent gynecology, and more.
- Authors are selected for their expertise; you'll benefit from their balanced perspective on the topic and their wealth of clinical experience.
- Each article is extensively referenced, saving you hours of library research.

Stay at the forefront of your specialty! Subscribe today by returning the order form or by calling our toll-free number.

Yes! Please begin my subscription to ***Current Problems in Obstetrics, Gynecology and Fertility*** (6 issues per year).

1991 Rates	U.S.A.	Canada	International

CLINICAL SECTION

Clinical Opinion

Fertility retention in the patient with genital prolapse 1155
David H. Nichols, MD
Providence, Rhode Island

Transabdominal construction of a sacrocervical ligament can relieve a uterine prolapse in the patient who wishes to preserve fertility.

The contributions of the nurse and the machine in home uterine activity monitoring systems 1159
Ruth B. Merkatz, PhD, RN, and Irwin R. Merkatz, MD
Bronx, New York

The reported efficacy of programs of home uterine activity monitoring is reanalyzed with respect to a dynamic interface among nurse, patient, and technology.

Clinical Articles

Bleeding patterns during continuous combined estrogen-progestogen therapy 1163
Ulla Marslew, MD, Bente J. Riis, MD, and Claus Christiansen, MD
Glostrup, Denmark

The major discrepancy between two continuous combinations of estrogen and progestogen was control of bleeding, which seemed to depend on the interaction between the components.

Effect of low-dose aspirin on vascular refractoriness in angiotensin-sensitive primigravid women 1169
Henk C.S. Wallenburg, MD, PhD, Guus A. Dekker, MD, PhD, Jolande W. Makovitz, MD, and Nel Rotmans, BSc
Rotterdam, The Netherlands

Low-dose aspirin, but not placebo, restores refractoriness to the vasopressor effects of infused angiotensin II in the majority of normotensive angiotensin-sensitive primigravid women.

Morphologic changes in the human amnion epithelium that accompany labor as seen with scanning and transmission electron microscopy 1174
Jiri Sonek, MD, Steven G. Gabbe, MD, Jay D. Iams, MD, and Douglas A. Kniss, PhD
Columbus, Ohio

Electron microscopic analysis of fetal membranes from elective cesarean sections and spontaneous vaginal deliveries reveals that human amnion epithelium undergoes morphologic changes during the course of labor.

Fibrocystic disease of the breast in premenopausal women: Histohormonal correlation and response to luteinizing hormone releasing hormone analog treatment 1181
Joseph Monsonego, MD, Marie-Dominique Destable, MD, Georges De Saint Florent, MD, Jacques Amouroux, MD, Jean-Claude Kouyoumdjian, MD, France Haour, PhD, Jean-Luc Breau, MD, Lucien Israel, MD, Ana-Maria Comaru-Schally, MD, and Andrew V. Schally, PhD, MD
Bobigny, Creteil, and Paris, France, and New Orleans, Louisiana

Chronic mastopathy, particularly when associated with uterine fibroma, can be successfully treated by luteinizing hormone releasing hormone analogs in premenopausal women.

Fast-scan magnetic resonance imaging in fetal visualization 1190
Anne S. Garden, MB, ChB, Richard D. Griffiths, MD, A. Michael Weindling, MD, and Peter A. Martin, PhD
Liverpool, United Kingdom

The use of a fast-scan magnetic resonance imaging technique allowed superior fetal visualization because of decreased motion artifact.

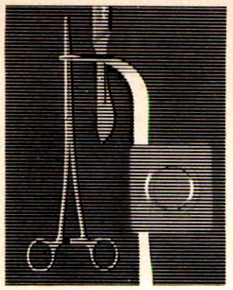
CEFOTAN® IM/IV



(cefotetan disodium)

In intra-abdominal and gynecologic infection due to indicated organisms

For Intravenous or Intramuscular Use
BRIEF SUMMARY

INDICATIONS AND USAGE
TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:
Urinary tract infections caused by *E coli, Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris, Providencia rettgeri,* and *Morganella morganii*).
Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli.*
Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli.*
Gynecologic infections caused by *Staphylococcus aureus** (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus* species (excluding enterococci), *E coli, Proteus mirabilis, Neisseria gonorrhoeae, Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*), *Fusobacterium* species,* and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species*).
Intra-abdominal infections caused by *E coli, Klebsiella* species (including *K pneumoniae**), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*).
Bone and joint infections caused by *Staphylococcus aureus.**
*Efficacy for this organism in this organ system was studied in fewer than ten infections.

Specimens for bacteriological examination should be obtained in order to isolate and identify causative organisms and to determine their susceptibilities to cefotetan. Therapy may be instituted before results of susceptibility studies are known; however, once these results become available, the antibiotic treatment should be adjusted accordingly.

In cases of confirmed or suspected gram-positive or gram-negative sepsis or in patients with other serious infections in which the causative organism has not been identified, it is possible to use CEFOTAN concomitantly with an aminoglycoside. Cefotetan combinations with aminoglycosides have been shown to be synergistic in vitro against many Enterobacteriaceae and also some other gram-negative bacteria. The dosage recommended in the labeling of both antibiotics may be given and depends on the severity of the infection and the patient's condition.

NOTE: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycosidic antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS
CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS
Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile.* Other causes should also be considered.

PRECAUTIONS
GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment or poor nutritional state, the elderly and patients with cancer. Prothrombin times should be monitored in patients at risk and exogenous vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc.) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

DRUG INTERACTIONS: Although to date nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels by Jaffe reaction and produce false increases in the levels of creatinine reported.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approximately 8-16 times the usual adult human dose) on days 6-35 of life (thought to be

developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approximately 2-4 times the usual human dose) only 1 of 10 treated animals was affected, and the degree of degeneration was mild.

Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
In clinical studies, the following adverse effects were considered related to CEFOTAN therapy.
Gastrointestinal symptoms occurred in 1.5% of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).
Hematologic laboratory abnormalities occurred in 1.4% of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).
Hepatic enzyme elevations occurred in 1.2% of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).
Hypersensitivity reactions were reported in 1.2% of patients and included rash (1 in 150) and itching (1 in 700).
Local effects were reported in less than 1.0% of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500). During postmarketing experience with CEFOTAN, anaphylactic reactions and transient thrombocytopenia have been reported.

DOSAGE AND ADMINISTRATION
TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dosage*	Every 12 hours
10-30	Usual Recommended Dosage*	Every 24 hours
<10	Usual Recommended Dosage*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Alternatively, the dosing interval may remain constant at 12 hour intervals, but the dose reduced to one-half the usual recommended dose for patients with a creatinine clearance of 10-30 mL/min, and one-quarter the usual recommended dose for patients with a creatinine clearance of less than 10 mL/min.

When only serum creatinine levels are available, creatinine clearance may be calculated from the following formula. The serum creatinine level should represent a steady state of renal function.

$$\text{Males:} \quad \frac{\text{Weight (kg)} \times (140 - \text{age})}{72 \times \text{serum creatinine (mg/100 mL)}}$$

$$\text{Females:} \quad 0.9 \times \text{value for males}$$

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED
CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. CEFOTAN is also available in a pharmacy bulk package of 10 g in 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.

1 g in 10 mL vial (NDC 0038-0376-10); 2 g in 20 mL vial (NDC 0038-0377-20); 1 g in 100 mL vial (NDC 0038-0376-11); 2 g in 100 mL vial (NDC 0038-0377-21); 10 g in 100 mL vial (NDC 0038-0375-10).

The N-terminal and C-terminal portions of the atrial natriuretic factor prohormone increase during preeclampsia 1197
Rhene W. Merkouris, MD, Frank C. Miller, MD, Val Catanzarite, MD, PhD, J. Gerald Quirk, Jr., MD, PhD, Lee A. Rigg, MD, PhD, and David L. Vesely, MD, PhD
Little Rock, Arkansas, and Tampa, Florida

Both the amino terminus (N-terminus) and the carboxy terminus (C-terminus) of the atrial natriuretic factor prohormone markedly increase during preeclampsia; both decrease immediately post partum.

Gestational age in relation to marine *n*-3 fatty acids in maternal erythrocytes: A study of women in the Faroe Islands and Denmark 1203
Sjúrður F. Olsen, MD, MSc, Harald S. Hansen, Dr.Scient., Steffen Sommer, MD, Benny Jensen, Lic.Tecn., Thorkild I.A. Sørensen, Dr.Med.Sci., Niels J. Secher, MD, and Petur Zachariassen, Cand.Scient.
Tórshavn, Faroe Islands, and Aarhus and Copenhagen, Denmark

The level of marine *n*-3 fatty acids in erythrocytes, which reflects dietary intake, is associated with gestational age in Danish women but not in Faroese women.

Recurrent failure of in vitro fertilization: Role of the hemizona assay in the sequential diagnosis of specific sperm-oocyte defects 1210
Sergio Oehninger, MD, Anibal A. Acosta, MD, Lucinda L. Veeck, MLT, Robert Brzyski, MD, PhD, Thinus F. Kruger, MD, Suheil J. Muasher, MD, and Gary D. Hodgen, PhD
Norfolk, Virginia, and Tygerberg, Republic of South Africa

The hemizona assay in sequence with other bioassays and in vitro fertilization results can provide specific sperm defect analysis in cases of fertilization failure.

Umbilical vein administration of oxytocin for the management of retained placenta: Is it effective? 1216
Maarten G.P. Huber, MD, Hajo I.J. Wildschut, MD, PhD, Kees Boer, MD, PhD, Gunilla Kleiverda, MD, and Frans J. Hoek, PhD
Amsterdam, The Netherlands, and Bristol, United Kingdom

In a multicenter randomized controlled trial involving 220 women with retained placenta, intraumbilical injection of oxytocin did not reduce either the percentage of placentas manually removed or the blood loss in the third stage.

The role of the transcerebellar view in the detection of fetal central nervous system anomaly 1220
Lyndon M. Hill, MD, Jerry G. Martin, MD, Joanne Fries, RDMS, and Joyce Hixson, RDMS
Pittsburgh, Pennsylvania

A transcerebellar view should be incorporated into all obstetric ultrasonographic examinations.

CA 125 levels in abruptio placentae 1225
Barry R. Witt, MD, Rachel Miles, MD, Gordon C. Wolf, PhD, MD, George T. Koulianos, MD, and Ian H. Thorneycroft, PhD, MD
New Orleans, Louisiana

Patients with bleeding in late pregnancy because of abruptio placentae had significantly elevated serum CA 125 levels compared with similar subjects with vaginal bleeding of other causes.

Management of severe preeclampsia detected in early labor by prostaglandin A_1 or dihydralazine infusions 1229
Mokhtar K. Toppozada, MD, Emad Darwish, MD, and Azza A.T. Barakat, MS
Alexandria, Egypt

Both prostaglandin A_1 and dihydralazine infusions induce a similar hypotensive response in severe preeclampsia encountered in early labor; the more gradual reduction of blood pressure and shorter time to delivery with prostaglandin A_1 are additional clinical advantages.

The intrauterine probe electrode 1233
Thomas H. Strong, Jr., MD, Richard H. Paul, MD, George D. Park, Yi Cheng, PhD, Donald E. Lewis, Dorothy F. McCart, RN, and Evelyn A. Mueller, RN
Los Angeles and Pomona, California

A device capable of detecting the fetal electrocardiogram for fetal heart rate derivation without fetal skin penetration is described.

Management of radionecrosis of the vulva and distal vagina 1235
William S. Roberts, MD, Mitchel S. Hoffman, MD, James P. LaPolla, MD, Ernesto Ruas, MD, James V. Fiorica, MD, and Denis Cavanagh, MD
Tampa, Florida

Radionecrosis of the vulva requires wide excision and appropriate tissue coverage to accomplish healing.

Cocaine and the use of alcohol and other drugs during pregnancy 1239
Ann P. Streissguth, PhD, Therese M. Grant, MEd, Helen M. Barr, MS, Zane A. Brown, MD, Joan C. Martin, PhD, Dennis E. Mayock, MD, Sharon Landesman Ramey, PhD, and Leejon Moore, MD
Seattle, Washington, and Birmingham, Alabama

Cocaine use during pregnancy was reported by 15% of a teaching hospital sample and 3% of a private hospital sample of mothers at delivery.

Fetal thyroid-stimulating hormone response to maternal administration of thyrotropin-releasing hormone 1244
J.G. Thorpe-Beeston, MD, K.H. Nicolaides, MD, R.J.M. Snijders, MSc, J. Butler, MA, and A.M. McGregor, MD
London, England

Injection of thyrotropin-releasing hormone to pregnant women at 25 to 37 weeks' gestation was associated with a rapid increase in fetal blood thyroid-stimulating hormone concentration.

(Contents continued on page 12A)

Contents continued from page 11A

In utero diagnosis and management of fetal subdural hematoma 1246
Siegfried Rotmensch, MD, Peter A. Grannum, MD, José A. Nores, MD, Cynthia Hall, MD, Marc S. Keller, MD, Shirley McCarthy, MD, and John C. Hobbins, MD
New Haven, Connecticut

A case of fetal subdural hematoma is presented, and criteria for the in utero diagnosis and guidelines for management are discussed.

Calcium-regulating hormones and osteocalcin levels during pregnancy: A longitudinal study 1248
Katsuyoshi Seki, MD, Noriko Makimura, DMSc, Chieko Mitsui, BS, Junko Hirata, BS, and Ichiro Nagata, MD
Tokorozawa City, Saitama, Japan

Serum parathyroid hormone and osteocalcin values, which were low in early pregnancy, declined toward the middle of pregnancy but increased in late pregnancy.

The relationship between autoantibodies and intrauterine growth retardation in hypertensive disorders of pregnancy 1253
Albert El-Roeiy, MD, Stephen A. Myers, DO, and Norbert Gleicher, MD
Chicago, Illinois

Autoantibodies, especially antiphospholipid antibodies, were associated with intrauterine growth retardation in patients with preeclampsia and chronic hypertension.

Umbilical arterial and venous acid-base and blood gas values and the effect of chorioamnionitis on those values in a cohort of preterm infants 1261
Gary D.V. Hankins, Lt Col, USAF, MC, Russell R. Snyder, Lt Col, USAF, MC, and Edward R. Yeomans, Maj, USAF, MC
San Antonio, Texas

Chorioamnionitis has no significant effect on umbilical arterial acid-base or blood gas values in preterm infants whose courses are otherwise uncomplicated; additionally, chorioamnionitis did not increase the percentage of infants who were born with acidemia.

Cervical human papillomavirus deoxyribonucleic acid and cytologic evaluations in gynecologic outpatients 1265
Pekka Nieminen, MD, Valeria R.X. Soares, MSc, Markku Aho, MD, Ervo Vesterinen, MD, Eeva Savia, MD, Antti Vaheri, MC, and Jorma Paavonen, MD
Helsinki, Finland

Of 2668 gynecologic outpatients, 10.2% tested positive for cervical human papillomavirus deoxyribonucleic acid; 73% of women with positive human papillomavirus deoxyribonucleic acid results had normal cervical cytologic evaluations.

A prospective genetic study of complete and partial hydatidiform moles 1270
Sylvia D. Lawler, MD, Rosemary A. Fisher, PhD, and Joan Dent, SRN
London, England

This prospective genetic study of partial and complete hydatidiform moles relates diagnosis to the risk of development of a gestational trophoblastic tumor.

Contents

The effect of sterile water blocks on low back labor pain 1277
Birgitta Trolle, MD, Margrethe Møller, MD, Hanne Kronborg, and Søren Thomsen, MD
Aalborg, Denmark

In a double-blind randomized study, intracutaneous sterile water blocks significantly diminished low back pain.

Electronic fetal heart monitoring, auscultation, and neonatal outcome 1281
Patricia H. Ellison, MD, Mark Foster, MA, Margaret Sheridan-Pereira, MD, and Dermot MacDonald, MD
Denver, Colorado, and Dublin, Ireland

Late deceleration was the only fetal heart pattern that correlated highly with the following neonatal parameters: Apgar scores at 1 and 5 minutes, neurologic evaluations at 0 to 48 hours and 72 hours to 1 week, and the development of neonatal convulsions.

Cost-effectiveness of prenatal testing for *Chlamydia trachomatis* 1289
Mary D. Nettleman, MD, and Thomas A. Bell, MD, MPH
Iowa City, Iowa, and Seattle, Washington

Screening all pregnant women for chlamydia is not cost-effective, but the excess cost is modest when direct antigen tests are used.

Intraamniotic detection of *Chlamydia trachomatis* deoxyribonucleic acid sequences by polymerase chain reaction 1295
Chia C. Pao, PhD, Shu-Min Kao, BS, Han-Chow Wang, MD, and Cagge C. Lee, MD
Taipei, Taiwan, Republic of China

Chlamydia trachomatis deoxyribonucleic acid sequence was found by polymerase chain reaction in amniotic fluid of patients with urogenital chlamydial infections.

Birth weights of infants of black and white mothers without pregnancy complications 1299
Thomas C. Hulsey, MSPH, ScD, Abner H. Levkoff, MD, and Greg R. Alexander, MPH, ScD
Charleston, South Carolina, and Minneapolis, Minnesota

Controlling for differences in demographic characteristics and eliminating the potential influence of medical complications of pregnancy, the mean birth weight for black infants was significantly less than that for white infants.

Incidence of genital herpes simplex virus at the time of delivery in women with known risk factors 1303
Patrick M. Catalano, MD, Alice O. Merritt, RN, and Philip B. Mead, MD
Burlington, Vermont

Of pregnant women without symptoms who are at risk for development of maternal genital herpes simplex virus, 2.4% had positive cultures at the time of delivery.

(Contents continued on page 14A)

Contents continued from page 13A

The clinical utility of maternal body mass index in pregnancy 1306
Honor M. Wolfe, MD, Ivan E. Zador, PhD, Thomas L. Gross, MD, Susan S. Martier, MSSA, and Robert J. Sokol, MD
Detroit, Michigan, and Peoria, Illinois

Maternal body mass index offers little advantage over maternal weight for initial clinical perinatal risk assessment.

Complexes of activated protein C with α_1-antitrypsin in normal pregnancy and in severe preeclampsia 1310
Francisco España, PhD, Juan Gilabert, MD, PhD, Justo Aznar, MD, PhD, Amparo Estellés, MD, PhD, Takao Kobayashi, MD, and John H. Griffin, PhD
Valencia, Spain, and La Jolla, California

Evidence is provided for an enhancement of thrombin generation in pure severe preeclampsia compared with chronic hypertension and superimposed preeclampsia, as indicated by an increase in activated protein C/inhibitor complexes.

Current Development

Progress in pathogenesis and management of clinical intraamniotic infection 1317
Ronald S. Gibbs, MD, and Patrick Duff, MD
Denver, Colorado, and Gainesville, Florida

In the past 10 years, there has been major progress in our understanding of the pathogenesis, microbiology, and treatment of this common clinical condition.

BASIC SCIENCE SECTION

Synergistic effect of intraperitoneally administered calcium channel blockade and recombinant tissue plasminogen activator to prevent adhesion formation in an animal model 1327
Randall C. Dunn, MD, Alex J. Steinleitner, MD, and Hovey Lambert, PhD
Houston, Texas, and Miami Beach, Florida

A synergistic benefit of verapamil and recombinant tissue plasminogen activator to prevent postoperative adhesions was seen when administered continuously by means of an intraperitoneal osmotic pump.

Endothelin and neuropeptide Y are vasoconstrictors in human uterine blood vessels 1330
Gabriel Fried, MD, PhD, and Ulf Samuelson, MD, PhD
Stockholm, Sweden

The effect of two recently discovered polypeptides, endothelin and neuropeptide Y, has been examined in human uterine blood vessels; both peptides were found to have vasoconstrictor actions.

Contents

Behavioral changes in fetal sheep caused by vibroacoustic stimulation: The effects of cochlear ablation 1336
Michael J. Parkes, DPhil, Peter J. Moore, PhD, David R. Moore, PhD, Nicholas M. Fisk, MB, BS, and Mark A. Hanson, DPhil
Reading, England

Intense vibroacoustic stimulation of fetal sheep caused electrocortical desynchronization, but the effect was absent in four of five fetuses with cochlear ablation.

Magnesium sulfate–induced relaxation of uterine arteries from pregnant and nonpregnant patients 1344
Sharon H. Nelson, PhD, and Maya S. Suresh, MD
Galveston, Texas

Magnesium sulfate inhibited norepinephrine- and potassium chloride–induced contractions in uterine arteries from pregnant and nonpregnant patients.

Regulation of the immune response to *Candida albicans* by monocytes and progesterone 1351
Aliza Kalo-Klein, PhD, and Steven S. Witkin, PhD
New York, New York

Variations among persons in the lymphocyte proliferative response to *Candida albicans* are largely determined by monocytes.

Regulation of CA 125 production by amnion and WISH cells in culture 1355
Antonella Barbati, PhD, Lorena Broccucci, PhD, Maurizio M. Anceschi, MD, PhD, and Ermelando V. Cosmi, MD
Perugia, Italy

CA 125 was detected in medium of amnion and WISH cells in culture; its release was found to be regulated by various substances.

Calcium every day
Aerobics every wee
Bone loss every yea

She needs PREMARIN to help prevent further bone loss

Calcium[1] and exercise are not enough to prevent post-menopausal osteoporosis, since estrogen deficiency is the primary cause.[2] PREMARIN is the only brand of estrogen indicated to prevent further bone loss and in a recently published study has been shown to reduce the risk of hip fractures by as much as 66%.[3]

Early PREMARIN therapy offers the best protection

The most significant rate of bone loss occurs in early menopause. PREMARIN can help maintain bone mass, preventing the progression of osteoporosis and its consequences.

Protection continues as long as estrogen therapy continues

Clinical studies show that within three years of menopause when therapy is withdrawn, bone loss begins again.[4]

PREMARIN®

(conjugated estrogens tablets)

Proven benefits for menopause and beyond

Estrogens have been reported to increase the risk of endometrial carcinoma in postmenopausal women. Estrogens should not be used in women (or men) with any of the following conditions: known or suspected 1) pregnancy, 2) breast cancer, 3) estrogen-dependent neoplasia, 4) undiagnosed abnormal genital bleeding, 5) active thrombophlebitis or thromboembolic disorders.

See important information on adjacent page.

For moderate-to-severe vasomotor symptoms and for osteoporosis

For atrophic vaginitis

PREMARIN®
(conjugated estrogens)

Vaginal Cream

0.625 mg/g

BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION AND PATIENT INFORMATION, SEE PACKAGE CIRCULARS.)*

PREMARIN® Brand of conjugated estrogens tablets, USP
PREMARIN® Brand of conjugated estrogens Vaginal Cream, in a nonliquefying base

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.
Close clinical surveillance of all women taking estrogens is important. Adequate diagnostic measures including endometrial sampling when indicated should be undertaken to rule out malignancy in all cases of undiagnosed persistent or recurring abnormal vaginal bleeding. There is currently no evidence that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.
2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.
Estrogen therapy during pregnancy is associated with an increased risk of congenital defects in the reproductive organs of the male and female fetus, an increased risk of vaginal adenosis, squamous-cell dysplasia of the uterine cervix, and vaginal cancer in the female later in life. The 1985 DES Task Force concluded that women who used DES during their pregnancies may subsequently experience an increased risk of breast cancer. However, a causal relationship is still unproven, and the observed level of risk is similar to that for a number of other breast cancer risk factors.
There is no indication for estrogen therapy during pregnancy. Estrogens are ineffective for the prevention or treatment of threatened or habitual abortion.

DESCRIPTION: PREMARIN (conjugated estrogens, USP) contains a mixture of estrogens, obtained exclusively from natural sources, blended to represent the average composition of material derived from pregnant mares' urine. It contains estrone, equilin, and 17α-dihydroequilin, together with smaller amounts of 17α-estradiol, equilenin, and 17α-dihydroequilenin as salts of their sulfate esters. Tablets are available in 0.3 mg, 0.625 mg, 0.9 mg, 1.25 mg, and 2.5 mg strengths of conjugated estrogens. Cream is available as 0.625 mg conjugated estrogens per gram.

INDICATIONS AND USAGE: Moderate-to-severe vasomotor symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression which might occur during menopause and they should not be used to treat these conditions.) Prevention and management of osteoporosis (abnormally low bone mass). Atrophic vaginitis. Atrophic urethritis. Hypoestrogenism due to hypogonadism, castration or primary ovarian failure.

PREMARIN (conjugated estrogens) Vaginal Cream is indicated in the treatment of atrophic vaginitis and kraurosis vulvae.

PREMARIN HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

CONTRAINDICATIONS: Estrogens should not be used in women (or men) with any of the following conditions: 1. Known or suspected pregnancy (see Boxed Warning). 2. Known or suspected cancer of the breast except in appropriately selected patients being treated for metastatic disease. 3. Known or suspected estrogen-dependent neoplasia. 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thromboembolic disorders. 6. Estrogen replacement therapy has not been reported to increase the risk of thrombophlebitis and/or thromboembolic disease. However, there is insufficient information regarding women who have had previous thromboembolic disease.

PREMARIN Tablets and Vaginal Cream should not be used in patients hypersensitive to their ingredients.

WARNINGS: Some studies suggest a possible increased incidence of breast cancer in women taking higher doses of estrogen for prolonged time periods. The majority of studies have not shown an association with usual estrogen replacement doses. Endometrial cancer risk among estrogen users was about 4-fold or greater than in non-users, and appears dependent on treatment duration and estrogen dose. In patients on combined estrogen-progestin therapy, this risk appears to be decreased. (See PRECAUTIONS below.)

Estrogen therapy during pregnancy is associated with an increased risk of fetal congenital reproductive tract disorders.

A 2.5-fold increase in the risk of surgically confirmed gall bladder disease in women receiving postmenopausal estrogens has been reported.

Large doses of estrogen such as those used to treat prostate and breast cancer have been shown to increase the risk of non-fatal myocardial infarction, pulmonary embolism, and thrombophlebitis in men. This cannot necessarily be extrapolated to women. However, to avoid theoretical cardiovascular risk caused by high estrogen doses, the doses for estrogen replacement therapy should not exceed the recommended dose.

Blood pressure should be monitored with estrogen use, especially if high doses are used.

Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases.

PRECAUTIONS: The addition of a progestin for 7 or more days of a cycle of estrogen administration reportedly lowers the incidence of endometrial hyperplasia. Studies of endometrium suggest that 10 to 13 days of progestin are needed to provide maximal endometrial maturation and elimination of hyperplastic changes. Additional risk, such as adverse effects on carbohydrate and lipid metabolism, may be associated with the inclusion of progestin in estrogen replacement regimens. The choice of progestin and dosage may be important in minimizing these adverse effects.

Physical examination and a complete medical and family history should be taken prior to the initiation of any estrogen therapy with special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolaou smear. As a general rule, estrogen should not be prescribed for longer than one yea without another physical examination being performed. Conditions influenced by fluid retention, such as asthma epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patients may develo manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding an mastodynia. Pre-existing uterine leiomyomata may increase in size during estrogen use. Estrogens should b used with care in patients with impaired liver function, renal insufficiency, or metabolic bone diseases associate with hypercalcemia.

The following drug/laboratory test interactions have been reported, some only with estrogen-progesti combinations (oral contraceptives):

1. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine induced platelet aggregability.
2. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, a measured by T_4 levels determined by column or by radioimmunoassay. Free T_3 resin uptake is decreased reflecting the elevated TBG; free T_4 concentration is unaltered.
3. Impaired glucose tolerance.
4. Reduced response to metyrapone test.
5. Reduced serum folate concentration.

MUTAGENESIS AND CARCINOGENESIS: Long-term, continuous administration of natural and syntheti estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and live

PREGNANCY CATEGORY X: Estrogens should not be used during pregnancy. See **CONTRAINDICATION** and Boxed Warning.

NURSING MOTHERS: As a general principle, the administration of any drug to nursing mothers should be don only when clearly necessary since many drugs are excreted in human milk.

ADVERSE REACTIONS: The following have been reported with estrogenic therapy; changes in vaginal bleedin pattern and abnormal withdrawal bleeding or flow, breakthrough bleeding, spotting, increase in size of uterin fibromyomata, vaginal candidiasis, change in amount of cervical secretion; tenderness or enlargement of breast nausea, vomiting, abdominal cramps, bloating, cholestatic jaundice; chloasma or melasma that may persist whe drug is discontinued, erythema multiforme, erythema nodosum, hemorrhagic eruption, loss of scalp hai hirsutism; steepening of corneal curvature, intolerance to contact lenses; headache, migraine, dizziness, menta depression, chorea; increase or decrease in weight; reduced carbohydrate tolerance; aggravation of porphyri edema; changes in libido.

ACUTE OVERDOSAGE: May cause nausea and vomiting.

DOSAGE AND ADMINISTRATION:

PREMARIN® Brand of conjugated estrogens tablets, USP

1. *Given cyclically for short-term use only.* For treatment of moderate-to-severe vasomotor symptoms, atrophi vaginitis, or atrophic urethritis associated with the menopause (0.3 mg to 1.25 mg or more daily). The lowest dos that will control symptoms should be chosen and medication should be discontinued as promptly as possible Administration should be cyclic (eg, three weeks on and one week off). Attempts to discontinue or tape medication should be made at three- to six-month intervals.
2. *Given cyclically:* Hypoestrogenism. Osteoporosis.

Hypoestrogenism due to: Female hypogonadism—2.5 mg to 7.5 mg daily in divided doses for 20 day followed by 10 day rest period. If bleeding does not occur by the end of this period, the same dosage schedule i repeated. Female castration or primary ovarian failure—1.25 mg daily, cyclically. Adjust upward or downwar according to response of the patient. For maintenance, adjust dosage to lowest level that will provide effectiv control.

Osteoporosis—0.625 mg daily. Administration should be cyclic (eg, three weeks on and one week off).

PREMARIN® Brand of conjugated estrogens Vaginal Cream

Given cyclically for short-term use only. For treatment of atrophic vaginitis or kraurosis vulvae.

The lowest dose that will control symptoms should be chosen and medication should be discontinued a promptly as possible.

Attempts to discontinue or taper medication should be made at three- to six-month intervals.

Usual dosage range: 2 g to 4 g daily, intravaginally, depending on the severity of the condition.

Patients with an intact uterus who are treated with either PREMARIN Tablets or Vaginal Cream should b monitored for signs of endometrial cancer and appropriate measures taken to rule out malignancy in the event persistent or recurring abnormal vaginal bleeding.

IN POSTPARTUM ENDOMETRITIS*

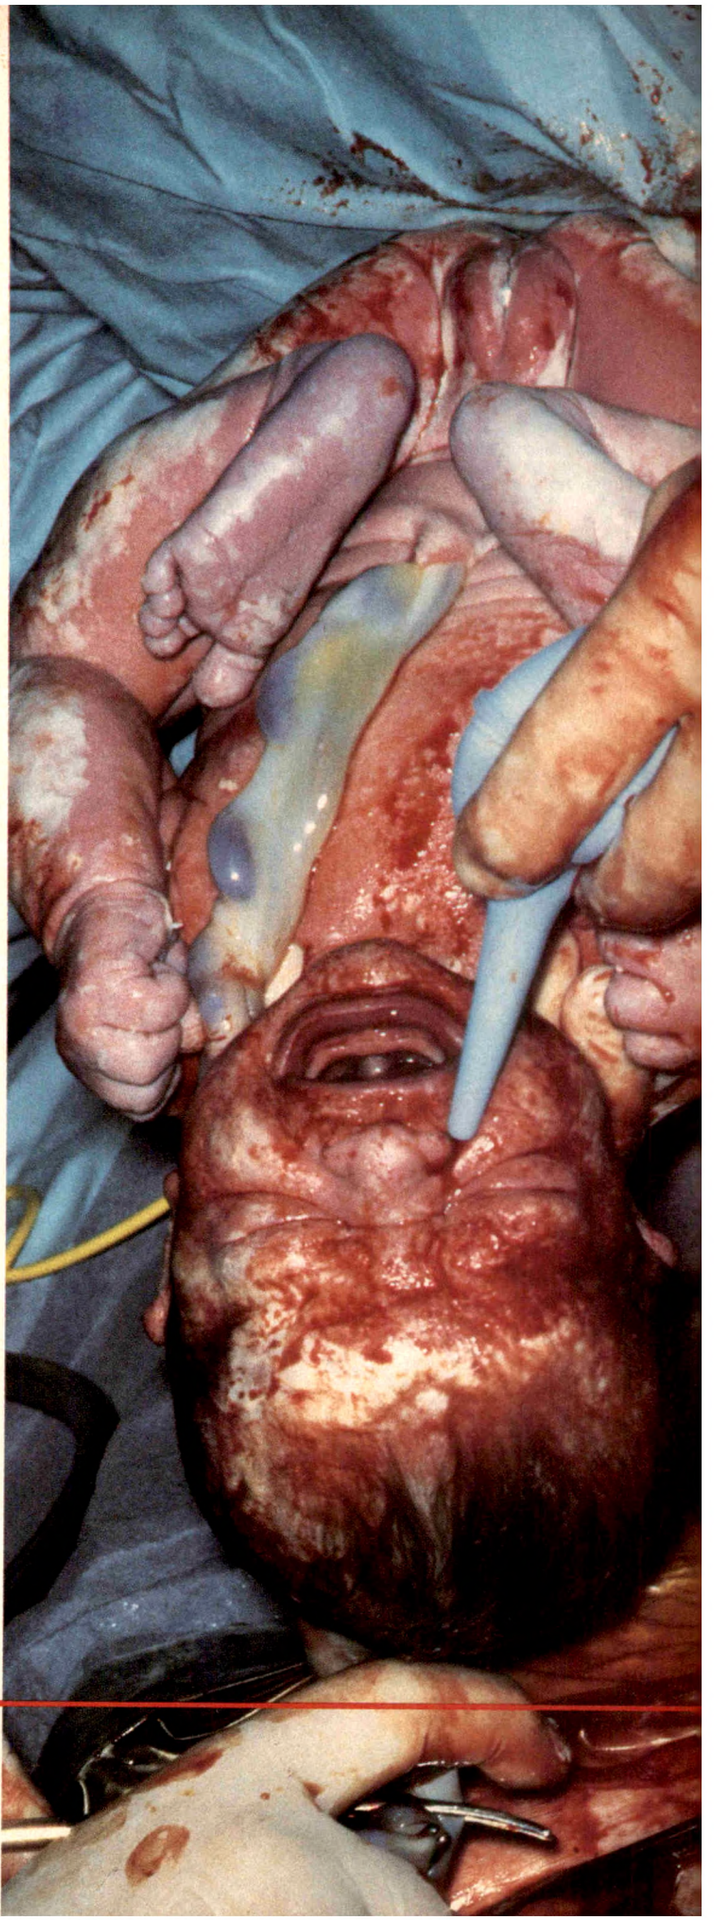
A randomized, comparative trial of AZACTAM versus gentamicin, each with clindamycin, for the treatment of endometritis after delivery.[1]

No universal criteria exist that may satisfy a single definition of "cure." Use of this term may vary between clinical settings and investigators, and the reader is urged to consult the reference listed.

Azactam®
aztreonam
delivers...

*Due to susceptible organisms.

†Although a useful guide, in vitro data do not necessarily correlate with therapeutic outcome.



‡Antibiotics should be given with caution to any patient who has had some form of allergy, particularly to drugs. See full prescribing information for recommendations on patients with immediate hypersensitivity reactions to penicillins.

Following IV administration, the most commonly seen adverse reactions occurred in less than 2% of patients, including local reactions, diarrhea, nausea, vomiting, and rash.

more than you're expecting...

- *Broad aerobic gram-negative in vitro coverage, including Escherichia coli, Proteus mirabilis, and Enterobacter cloacae.†*
- *Greater than 90% cure rates in combination with clindamycin.[1-3]*
- *No time-consuming, costly, routine therapeutic drug monitoring.*
- *May be admixed in the same bag with clindamycin.*
- *May be used in penicillin-allergic patients.‡*
- *Pregnancy Category B.*

There are no adequate and well-controlled studies in pregnant women. AZACTAM should be used in pregnant women only if clearly needed.

Azactam®
aztreonam

A logical alternative to aminoglycosides.

Please see adjacent page for brief summary of prescribing information.

Azactam®
aztreonam

AZACTAM® FOR INJECTION
Aztreonam For Injection

DESCRIPTION–AZACTAM (aztreonam, Squibb) is the first member of a new class of antibiotics classified as monobactams. AZACTAM is a totally synthetic bactericidal antibiotic with activity against a wide spectrum of gram-negative aerobic pathogens. The monobactams, having a unique monocyclic beta-lactam nucleus, are structurally different from other beta-lactam antibiotics.

AZACTAM For Injection is a sterile, nonpyrogenic, sodium-free, white to yellowish-white lyophilized cake, containing approximately 780 mg arginine per gram of aztreonam for intramuscular or intravenous use following constitution. Aqueous solutions of the product have a pH in the range of 4.5-7.5.

INDICATIONS AND USAGE–Before initiating treatment with AZACTAM, appropriate specimens should be obtained for isolation of the causative organism(s) and for determination of susceptibility to aztreonam. Treatment with AZACTAM may be started empirically before results of the susceptibility testing are available; subsequently, appropriate antibiotic therapy should be continued.

AZACTAM For Injection is indicated for the treatment of the following infections caused by susceptible gram-negative microorganisms: **Urinary Tract Infections** (complicated and uncomplicated), including pyelonephritis and cystitis (initial and recurrent) caused by *Escherichia coli, Klebsiella pneumoniae, Proteus mirabilis, Pseudomonas aeruginosa, Enterobacter cloacae, Klebsiella oxytoca*, Citrobacter* species* and *Serratia marcescens**. **Lower Respiratory Tract Infections,** including pneumonia and bronchitis caused by *Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Haemophilus influenzae, Proteus mirabilis, Enterobacter* species and *Serratia marcescens**. **Septicemia** caused by *Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Proteus mirabilis*, Serratia marcescens** and *Enterobacter* species. **Skin and Skin-Structure Infections,** including those associated with postoperative wounds, ulcers and burns caused by *Escherichia coli, Proteus mirabilis, Serratia marcescens, Enterobacter* species, *Pseudomonas aeruginosa, Klebsiella pneumoniae,* and *Citrobacter* species*. **Intra-abdominal Infections,** including peritonitis caused by *Escherichia coli, Klebsiella* species, including *K. pneumoniae, Enterobacter* species including *E. cloacae*, Pseudomonas aeruginosa, Citrobacter* species* including *C. freundii** and *Serratia* species* including *S. marcescens**. **Gynecologic Infections,** including endometritis and pelvic cellulitis caused by *Escherichia coli, Klebsiella pneumoniae*, Enterobacter* species* including *E. cloacae**, and *Proteus mirabilis**.

AZACTAM is indicated for adjunctive therapy to surgery in the management of infections caused by susceptible organisms, including abscesses, infections complicating hollow viscus perforations, cutaneous infections and infections of serous surfaces. AZACTAM is effective against most of the commonly encountered gram-negative aerobic pathogens seen in general surgery.

Concurrent Therapy–Concurrent initial therapy with other antimicrobial agents and AZACTAM is recommended before the causative organisms(s) is known in seriously ill patients who are also at risk of having an infection due to gram-positive aerobic pathogens. If anaerobic organisms are also suspected, therapy should be initiated using an antianaerobic agent concurrently with AZACTAM. Certain antibiotics (e.g., cefoxitin, imipenem) may induce high levels of beta-lactamase *in vitro* in some gram-negative aerobes such as *Enterobacter* and *Pseudomonas* species, resulting in antagonism to many beta-lactam antibiotics including aztreonam. These *in vitro* findings suggest that such beta-lactamase inducing antibiotics not be used concurrently with aztreonam. Following identification and susceptibility testing, appropriate antibiotic therapy should be continued.

CONTRAINDICATIONS–Aztreonam is contraindicated in patients with known allergy to this antibiotic.

WARNINGS–Pseudomembranous colitis has been reported with nearly all antibacterial agents, including aztreonam, and may range in severity from mild to life-threatening. Therefore, it is important to consider this diagnosis in patients who present with diarrhea subsequent to the administration of antibacterial agents.

Treatment with antibacterial agents alters the normal flora of the colon and may permit overgrowth of clostridia. Studies indicate that a toxin produced by *Clostridium difficile* is one primary cause of "antibiotic-associated colitis."

After the diagnosis of pseudomembranous colitis has been established, therapeutic measures should be initiated. Mild cases of pseudomembranous colitis usually respond to drug discontinuation alone. In moderate to severe cases, consideration should be given to management with fluids and electrolytes, protein supplementation, and treatment with an oral antibacterial drug effective against *C. difficile* (e.g., vancomycin). Careful inquiry should be made for a history of hypersensitivity reaction to any antibiotic or other drugs. Antibiotics should be given with caution to any patient who has had some form of allergy, particularly to drugs. It is recommended that patients who have had immediate hypersensitivity reactions (e.g., anaphylactic or urticarial) to penicillins and/or cephalosporins should be followed with special care. If an allergic reaction to aztreonam occurs, discontinue the drug and institute supportive treatment as appropriate (e.g., maintenance of ventilation, pressor amines, antihistamines, corticosteroids). Serious hypersensitivity reactions may require epinephrine and other emergency measures.

PRECAUTIONS–General: In patients with impaired hepatic or renal function, appropriate monitoring is recommended during therapy. If an aminoglycoside is used concurrently with aztreonam, especially if high dosages of the former are used or if therapy is prolonged, renal function should be monitored because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. The use of antibiotics may promote the overgrowth of nonsusceptible organisms, including gram-positive organisms and fungi. Should superinfection occur during therapy, appropriate measures should be taken.

Carcinogenesis, Mutagenesis, Impairment of Fertility–Carcinogenicity studies in animals have not been performed. Genetic toxicology studies performed *in vivo* and *in vitro* with aztreonam in several standard laboratory models revealed no evidence of mutagenic potential at the chromosomal or gene level. Two-generation reproduction studies in rats at daily doses up to 20 times the maximum recommended human dose, prior to and during gestation and lactation, revealed no evidence of impaired fertility. There was a slightly reduced survival rate during the lactation period in the offspring of rats that received the highest dosage, but not in offspring of rats that received five times the maximum recommended human dose.

Pregnancy–Pregnancy Category B: Aztreonam crosses the placenta and enters the fetal circulation. Studies in pregnant rats and rabbits, with daily doses up to 15 and 5 times, respectively, the maximum recommended human dose, revealed no evidence of embryo- or fetotoxicity or teratogenicity. No drug induced changes were seen in any of the maternal, fetal or neonatal parameters that were monitored in rats receiving 15 times the maximum recommended human dose of aztreonam during late gestation and lactation. There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, aztreonam should be used during pregnancy only if clearly needed.

Nursing Mothers–Aztreonam is excreted in breast milk in concentrations that are less than 1% of concentrations determined in simultaneously obtained maternal serum; consideration should be given to temporary discontinuation of nursing and use of formula feedings.

Pediatric Use–Safety and effectiveness have not been established in infants and children.

ADVERSE REACTIONS–Local reactions such as phlebitis/thrombophlebitis following IV administration, and discomfort/swelling at the injection site following IM administration occurred at rates of approximately 1.9% and 2.4%, respectively. Systemic reactions (considered to be related to therapy or of uncertain etiology) occurring at an incidence of 1 to 1.3% include diarrhea, nausea and/or vomiting, and rash. Reactions occurring at an incidence of less than 1% are listed within each body system in order of decreasing severity; *Hypersensitivity*–anaphylaxis. *Hematologic*–pancytopenia, neutropenia, thrombocytopenia, anemia, leukocytosis, thrombocytosis. *Gastrointestinal*–abdominal cramps; rare cases of *C. difficile*-associated diarrhea, including pseudomembranous colitis, or gastrointestinal bleeding have been reported. Onset of pseudomembranous colitis symptoms may occur during or after antibiotic treatment (see WARNINGS). *Dermatologic*–purpura, erythema multiforme, urticaria, exfoliative dermatitis, petechiae, pruritus, diaphoresis. *Cardiovascular*–hypotension, transient ECG changes (ventricular bigeminy and PVC). *Respiratory*–one patient experienced flushing, chest pain, and dyspnea. *Hepatobiliary*–hepatitis, jaundice. *Nervous System*–seizure, confusion, vertigo, paresthesia, insomnia, dizziness. *Musculoskeletal*–muscular aches. *Special Senses*–tinnitus, diplopia, mouth ulcer, altered taste, numb tongue, sneezing and nasal congestion, halitosis. *Other*–vaginal candidiasis, vaginitis, breast tenderness. *Body as a Whole*–weakness, headache, fever, malaise.

Adverse Laboratory Changes–Those reported without regard to drug relationship during clinical trials were: *Hepatic*–elevations of AST (SGOT), ALT (SGPT), and alkaline phosphatase; signs or symptoms of hepatobiliary dysfunction occurred in less than 1% of recipients (see above). *Hemic*–increases in prothrombin and partial thromboplastin times, eosinophilia, positive Coombs test. *Renal*–increases in serum creatinine.

OVERDOSAGE–If necessary, aztreonam may be cleared from the serum by hemodialysis and/or peritoneal dialysis.

DOSAGE AND ADMINISTRATION–Dosage adjustments are recommended for patients with impaired renal function. In elderly patients, estimates of creatinine clearance should be obtained and appropriate dosage modifications made if necessary.

HOW SUPPLIED–AZACTAM For Injection (Aztreonam For Injection)–Lyophilized–is supplied in single-dose 15 mL vials containing **500 mg,** or **1 g**/vial; in single-dose 30 mL vials containing **2 g**/vial; and in single-dose 100 mL intravenous infusion bottles containing **500 mg** or **1 g** or **2 g**/bottle.

Consult package insert before prescribing AZACTAM (aztreonam). (J4-231C)

*Efficacy for this organism in this organ system was studied in fewer than ten infections.

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1988;108:258-65. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL.

Manuscript submission. Manuscripts should be submitted to one of the two Editors in Chief as follows:

1. **Dr. Zuspan**—manuscripts from the eastern United States and from England, Israel, and Italy, manuscripts written for Clinical Opinion and Current Development, Letters to the Editors, and all manuscripts presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation. *Manuscripts from The Society of Perinatal Obstetricians should be submitted to Dr. Donald R. Coustan, Department of Obstetrics and Gynecology, Women and Infants Hospital of Rhode Island, 101 Dudley St., Providence, RI 02905.*
2. **Dr. Quilligan**—manuscripts from states west of Pennsylvania, West Virginia, Kentucky, Tennessee, and Mississippi; manuscripts from Hawaii, Alaska, Canada, and abroad (except England, Israel, and Italy). Dr. Quilligan is responsible for manuscripts from the Society for Gynecologic Investigation. *Manuscripts from the Society for Gynecologic Investigation should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033.*

Author's designation of reviewers. When authors submit their manuscripts, they should provide the names and addresses of at least three reviewers for consideration by the Editors.

Copyright statement. The specified copyright statement that follows the Information for Authors in each issue of the JOURNAL must be completed, signed by all authors, and submitted with the manuscript. (The Checklist and Copyright Statement may be torn from the JOURNAL or photocopied for submission.) If not completed in full, it will be returned to the author for completion.

Checklist. The checklist that appears with the copyright statement in each issue of the JOURNAL must be fully completed by the author(s) and sent with each submitted manuscript. A more complete description of each item that must be checked is provided under the appropriate heading in the Information for Authors, which is published in each issue of the JOURNAL. *If the checklist is not completed in full, the deficiencies will be noted, and the form, as well as the manuscript when necessary, will be returned to the author for completion.*

Previous publication. If a report by the same author(s) has been previously published in any medium that deals in any respect whatever with the same patients, same animals, same laboratory experiments, or same data, in part or in full, as those reported in the manuscript being submitted, two reprints of the article or two copies of the manuscript, be it a full-length report or an abstract, must be submitted with the manuscript. The author(s) should inform the Editor of the circumstances, similarities, and differences of the reports. This requirement also applies to the submission of a manuscript in which a few different patients, animals, laboratory experiments, or data were added to those reported in a previous publication or in a submitted or accepted manuscript. Articles previously published in another language will not be considered.

Human and animal experimentation. It is assumed by the Editors that manuscripts emanating from a particular institution are submitted with the approval of the requisite authority. Human experimentation that requires local institutional approval must have this approval *before the ex-*

periment is started and approval must be so indicated in the Methods section of the submitted manuscript. Reports of experiments on animals must *state in the Methods section of the manuscript* that the guidelines for the care and use of the animals *approved by the local institution* were followed. The species of nonhuman animals used in an investigation must be named in the title, abstract, and key words of the manuscript.

Authorship. For manuscripts with two or more authors, each author must qualify by having participated actively and sufficiently in the study that is being performed and reported. The inclusion of each author in the authorship list of a report is based only (1) on substantial contributions to (a) concept and design, or analysis and interpretation of data and (b) drafting the manuscript or revising it critically for important intellectual content; and (2) on final approval by each author of the version of the manuscript. Conditions 1 (a and b) and 2 must both be met. Others contributing to the work should be recognized separately in an Acknowledgment. In the covering letter that accompanies the submitted manuscript, it must be confirmed that all authors fulfilled both conditions.

Conflict of interest. Authors are expected to inform the Editor, in a letter accompanying the submitted manuscript, of any commercial association that might pose a conflict of interest, such as ownership, stock holdings, equity interests and consultant activities, or patent-licensing situations. Such information is confidential, is not given to the consultants, and does not play a part in the decision of the quality or timeliness of the manuscript. If the manuscript is accepted, the author and the Editor will determine how best to release the information. The usual and customary listing of sources of support and institutional affiliations on the title page is proper and does not imply a conflict of interest; only where there is a possible conflict of interest is the author(s) expected to inform the Editor.

Disclaimer. Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher, and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality photocopies of the manuscript and three sets of glossy prints of illustrations are required.

Manuscripts must be typed double-spaced on one side only of 22 × 28 cm (8½ × 11 inch) white bond paper with 1-inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, condensation, abstract, body of text, acknowledgments, references, figure legends, and tables.

Title page. The title page (page 1) should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of each author and each author's highest academic degree (both MD and PhD are acceptable, but honors degrees are not permitted); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; source(s) of financial support; presented line, if applicable; disclaimers, if any; name, address, business and home telephone numbers, and fax number of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name, address, business and home telephone numbers, and fax number of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Condensation. On page 2 of the manuscript provide a brief, concise condensation, typed double-spaced, that will appear with the title in publication of the Contents pages of the JOURNAL. It should be a single-spaced sentence, limited to a maximum of 25 words, delineating the essential point(s) made in the manuscript.

Abstract page and key words/phrases. On manuscript page 3, type the abstract, double-spaced, with the required margins and headed by the title of the article and name(s) of author(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations, since the emphasis is on the "action" rather than on the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors*. Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods* section describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

In the *Results* section present the detailed findings. Include mentions of all tables and/or figures. Figures and tables should supplement, not duplicate, the text; presentation of data in either one or the other will suffice. Emphasize only your important observations; do not compare

Estimating length of manuscripts

With the exception of Current Development articles, the length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A text of 4200 words or more can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7-page article in the JOURNAL. The 2000 words of text alone makes approximately 8 pages of manuscript typed double-spaced with the required 1-inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 words in manuscript. Thus, if a greater number of illustrations and tables is used, the length of the text should be adjusted accordingly.

your observations with those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment* section state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number (25) is allowed, except in case reports and brief communications (limited to 2) and in manuscripts for the Current Development section (for which there is no limit). Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" (Vancouver style) (Ann Intern Med 1988;108:258-65). Journal titles should conform to abbreviations used in *Cumulated Index Medicus*.

Examples (if six or fewer authors, list all; if seven or more authors, list three then et al.):

JOURNAL: Flamm BL, Dunnett C, Fischermann E, Quilligan EJ. Vaginal delivery following cesarean section: use of oxytocin augmentation and epidural anesthesia with internal tocodynamic and internal fetal monitoring. AM J OBSTET GYNECOL 1984;148:759-63.

BOOKS: Ledger WJ. Dystocia and prolonged labor. In: Wilson JR, Carrington ER, eds. Obstetrics and gynecology. St. Louis: CV Mosby, 1987 vol 8:474-93.

Personal communications and unpublished data, if essential, may be used but not as numbered references. If they are used, they are to be referred to, within parentheses, at the appropriate location in the text. If used, the author(s) must obtain written and signed permission for their use from the individual being quoted. This signed permission must accompany the manuscript when it is submitted to the Editor. Published abstracts can be used as numbered references; however, reference to the complete published article is preferred.

Figures. The term *figure* includes all types of illustrations such as graphs, diagrams, photographs, flow charts, and line drawings. A reasonable number of figures will be reproduced without charge, but special arrangements must be made with the Editors for color figures at an additional charge to the author. The quoted charge is per page of color, and as many as eight color figures can be included on one page.

Figures must be cited consecutively in the text in Arabic numerals and identified with a gummed label on the back of the figure with author(s) name(s), title of article, figure number, and top marked clearly. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted. Do not use paper clips or mar the surface of figures in any way. Figures will be returned only on request by the author.

For *black-and-white figures,* submit three sets of 3 × 4 inch (minimum) to 5 × 7 inch (maximum) unmounted, glossy prints. All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy prints with good black-and-white contrast.

For *color figures* submit original transparencies and two sets of unmounted prints on glossy (smooth surface) paper. Polaroid prints are not acceptable. Color transparencies must have a color balance (consistency in lighting and film speed) that is acceptable to the author and Editors before acceptance for publication. Please note that 35 mm transparencies are enlarged to twice their original size. If it is important to deviate from this standard, please so indicate when the material is submitted. The top, first author's last name, and figure number must be indicated on the front of each transparency and the back of each print.

Computer-generated figures must be legible and clearly printed in jet black ink on heavy coated paper with either a glossy or dull finish. Any patterns or shadings must be dark enough for reproduction and must be distinguishable from each other. Lines, symbols, and letters should be both smooth and complete. The legend should not appear on the figure. On the back of each figure the name of the first author and the figure number should be given and the top indicated. Three original individual laser or plotter prints are to be submitted *unmounted* with the manuscript. Laser prints should be full size at 300 dots per inch (DPI) or greater full-page resolution; multiple illustrations on a page cannot be accepted. Dot matrix prints and photographic halftones are not acceptable. *Color figures* are acceptable, but special arrangements must be made with the Editors. The colors used must be dark enough and of sufficient contrast for reproduction. With the exception of fluorescent colors, all colors can be reproduced in four-color figures. The preparation and submitting of color prints should fol-

low the preceding guidelines for black-and-white computer-generated illustrations.

Legends to figures. Legends for all figures must be typed double-spaced on paper separate from the text of the manuscript, and these pages must be numbered in sequence after the references. Titles should be included in the legend, not on the print. Original magnifications should be provided. If a figure has been taken from copyrighted material, the legend must give full credit to the original source.

Tables. Tables should be typed on separate sheets of paper, one table to a page, and included at the end of the text. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Titles should be brief yet indicate clearly the purpose or content of each table, and each column should be precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. If a table or any part thereof has been taken from copyrighted material, a footnote to the table must give full credit to the original source. Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Permissions. Direct quotations, tables, or figures that have appeared in copyrighted material must be accompanied by written permission for their use from the copyright owner and original author along with complete information as to source. Photographs of identifiable persons must be accompanied by signed releases. If not, all recognizable features must be masked.

Requirements for manuscripts

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for regular article.

Clinical Opinion. Limit of 3000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Letters to the Editors. Letters to the Editors must be submitted in duplicate, typed double-spaced, and the text of the manuscript must be limited to a maximum of 400 words (excluding references, name(s) and address(es) of the signer(s), and the phrase "To the Editors"). The submitted Letter to the Editors must be accompanied by a signed copyright statement. If there are two or more signers of the Letter to the Editors, one of the authors may sign the copyright statement but must add to the statement the following: "I sign for and accept responsibility for releasing this letter on behalf of any and all co-signers." These requirements apply to all types of Letters to the Editors. Letters should be sent to Dr. Zuspan.

Two types of letters will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. If the original author does not respond, a notation indicating "Response declined" will be published. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60 U.S., and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Zuspan. No books will be returned.

Reprints

The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the Publisher with the author's consent.

Business communications

Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, or call Journal Advertising Production Manager (314) 872-8370.

CHECKLIST AND COPYRIGHT STATEMENT

Both the checklist and the copyright statement forms **must be completed** and sent with each submitted manuscript. If **not** completed, these forms will be returned to the author for completion.

These items appear in each monthly issue of the JOURNAL. A photocopy may be used. An exposition of the requirements given in the checklist is in the Information for Authors, which is published in each issue of the JOURNAL.

CHECKLIST

General

—The original and two copies of the manuscript are submitted.
—The appropriate signed completed checklist and assignment of copyright signed by **all** authors accompany the manuscript.
—Three sets of unmounted glossy prints for regular figures are submitted, properly numbered and labeled on the back of each print.
—Three sets of original computer-generated figures printed on heavy coated paper with either a glossy or dull finish, unmounted, each one on a page, and properly labeled on the back are submitted. None are dot matrix or photographic prints.
—Human experimentation has been approved by the local institution as stated in the Methods section.
—Guidelines for the care and use of animals approved by the institution have been followed as indicated in the Methods section.
—The covering letter with essential information is with the manuscript.
—All elements of the manuscript are typed double-spaced on bond paper with 1-inch margins at top, bottom, and sides.
—All pages are numbered in the following order: title page, condensation, abstract, body of the text, acknowledgments only of persons who have made substantive contributions to the study, references, legends, and tables.
—Signed, written permission from both the copyright holder and the original author for the use of tables, figures, or quotations previously published and their complete references are enclosed with the manuscript.
—Signed, written permission for the use of quotations of personal communications and unpublished data has been obtained from the person(s) being quoted and is enclosed.

Authorship

—In the covering letter that accompanies the submitted manuscript I/we have confirmed that all authors fulfilled both conditions required for authorship.

Conflict of interest

—In the covering letter that accompanies the submitted manuscript the commercial association of the author or of any co-authors that might pose a conflict of interest is described.

Previous publications

—Enclosed with the submitted manuscript are two reprints each of articles the author or co-authors have previously published or have in manuscript form dealing with same patients, same animals, same laboratory experiment, or same data, in part or in full, as those reported in the submitted manuscript. Further explanation is provided in the covering letter that accompanies the submitted manuscript.
—Similarities and differences are identified.

Reviewers

—Names and addresses of three individuals are enclosed.

Title page

—These elements are given in the following sequence, and are typed double-spaced.
—Title.
—Author(s) name(s) and highest academic degree(s) are shown.
—City(ies), state(s), and country other than U.S. in which the study was conducted are given.
—The name(s) of the institution(s) section(s), division(s), department(s) in which the study was performed is provided and the author(s) institutional affiliation at the time of the study is indicated.
—Acknowledgment of financial support is cited.
—Name, address, business and home telephone numbers, and fax number of author to whom requests for reprints are to be sent are included.
—If reprints will not be available, this has been stated on the title page.
—If the corresponding author is different from the author to whom reprint requests are to be sent, his/her name, address, business and home telephone numbers, and fax number have been added.
—At the bottom of the page, a running head not exceeding 52 characters (including word spaces) has been typed.

Condensation

—On a separate sheet of paper, page 2 of the manuscript, a single sentence limited to 25 words delineating the essential point(s) is typed double-spaced.

Abstract

—The abstract is typed double-spaced with required margins (on page 3) headed by the title and the author(s) name, not exceeding 150 words. For case reports and brief communications the limit of 50 words is not exceeded.
—Three to five key words or short phrases are placed beneath the abstract on page 3.

Tables

—Each table headed by a title and numbered in Roman numerals is typed double-spaced on a separate page.

—Tables are cited in sequence in the text.

Figures

—Each is numbered with an Arabic numeral and cited in numerical sequence in the text.

—Original transparencies of **color photographs** appropriately numbered and identified are submitted along with two sets of unmounted prints on glossy paper, numbered and identified on the back.

References

—Are typed double-spaced.

—Are numbered consecutively in the order they are cited in the text.

—The format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" is used. Examples shown in Information for Authors were followed.

—Personal communications and unpublished observations are not used as numbered references but are mentioned in the text with the written approval of the person being quoted. The signed approval is enclosed.

Triphasil®

Levonorgestrel and ethinyl estradiol tablets—
Triphasic regimen 21- and 28-day regimens

THE OC TO START WITH BECAUSE SHE'LL STAY WITH IT

IN BRIEF:
TRIPHASIL® — 6 brown tablets containing 0.050 mg levonorgestrel with 0.030 mg ethinyl estradiol; 5 white tablets containing 0.075 mg levonorgestrel with 0.040 mg ethinyl estradiol; 10 light-yellow tablets containing 0.125 mg levonorgestrel with 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day regimen) — Triphasic regimen.

Indications and Usage — TRIPHASIL® is indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OC's) as a method of contraception.

Contraindications — OC's should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during use of OC's or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thrombo-embolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners pre-scribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems* — An increased risk of thromboembolic and thrombotic disease associated with use of OC's is well established. Three principal studies in Great Britain and 3 in the U.S. have demonstrated increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OC's are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS — In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION (MI) — An increased risk of MI associated with the use of OC's has been reported, confirming a previously suspected association. These studies, conducted in the UK, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of pre-eclamptic toxemia) the higher the risk of developing MI, regardless of whether the patient was an OC user or not. OC's, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to MI) are about twice as likely to have a fatal MI as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal MI compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, amount of smoking is also an important factor. In determining importance of these relative risks, however, baseline rates for various age groups must be given serious consideration. Importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; quite likely the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE — In an analysis of data derived from several national adverse-reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to dose of estrogen in OC's. Preparations containing 100 mcg or more of estrogen were associated with higher risk of thromboembolism than those containing 50-80 mcg. Their analysis did suggest, however, that quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the U.S.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES — A large prospective study carried out in the UK estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OC's according to age, smoking habits, and duration of use. Overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34 — 5/100,000; ages 35-44 — 33/100,000; ages 45-49 — 140/100,000), risk being concentrated in older women, in those with long duration of use and in cigarette smokers. It was not possible, however, to examine interrelationships of age, smoking, and duration of use, nor to compare effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess magnitude of relative risk for this younger group. Available data from a variety of sources have been analyzed to estimate risk of death associated with various methods of contraception. Estimates of risk of death for each method include combined risk of contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OC's) plus risk attributable to pregnancy or abortion in event of method failure. This latter risk varies with effectiveness of method. The study concluded that mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OC's in women over 40 who smoke. Lowest mortality is associated with condom or diaphragm backed up by early abortion. Risk of thromboembolic and thrombotic disease associated with OC's increases with age after about 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of pre-eclamptic toxemia, and especially cigarette smoking. Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A 4- to 6-fold increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OC's should be discontinued at least 4 weeks before surgery of a type associated with increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS — Findings from one study in Britain involving cerebrovascular disease and another in the U.S. concerning MI suggest an increased risk of these conditions in users of OC's persists after discontinuation of the OC's. In the British study, risk of cerebrovascular disease remained elevated in former OC users for at least 6 years after discontinuation. In the U.S. study, increased risk of MI persisted for at least 9 years in women 40 to 49 years old who had used OC's for 5 or more years. Findings in both studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions* — There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with use of OC's. Discontinue OC's if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma* — Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in OC's, have been noted to increase incidence of mammary nodules, benign and malignant, in dogs. In humans, 3 case-control studies have reported an increased risk of endometrial carcinoma associated with prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OC's. Of cases found in women without predisposing risk factors (e.g., irregular bleeding at the time OC's were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These are no longer marketed. No evidence has been reported suggesting increased risk of endometrial cancer in users of conventional combination or progestogen-only OC's. Several studies have found no increase in breast cancer in women taking OC's or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women on OC's, found an excess risk in subgroups of OC users with documented benign breast disease. Reduced occurrence of benign breast tumors in users of OC's has been well documented. In summary, there is at present no confirmed evidence from human studies of increased risk of cancer associated with OC's. Close clinical surveillance of all women on OC's is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or with breast nodules, fibrocystic disease, or abnormal mammograms should be monitored with particular care if they elect to use OC's.

4. *Hepatic Tumors* — Benign hepatic adenomas have been found to be associated with use of OC's. One study showed that OC's with high hormonal potency were associated with higher risk than lower potency OC's. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users. Two studies relate risk with duration of use of OC's, the risk being much greater after 4 or more years' use. While hepatic adenoma is rare, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women on OC's. Relationship of these drugs to this type of malignancy is not known.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring* — Use of female sex hormones — both estrogenic and progestational agents — during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have increased risk of developing in later life a form of vaginal or cervical cancer ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence now that OC's further enhance risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OC's. Furthermore, 30 to 90% of such exposed women have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with use of other estrogens, it cannot be presumed they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with use of sex hormones, including OC's, in pregnancy. One case-control study estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OC's, hormonal withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some exposures involved only a few days. Data suggest that risk of limb-reduction defects in exposed fetuses is somewhat less than 1 in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OC's. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OC's is unknown. It is recommended that, for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing OC's. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at time of first missed period, and further use of OC's should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and advisability of continuation of the pregnancy should be discussed. It is also recommended that women who discontinue OC's with intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this. The administration of progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease* — Studies report increased risk of surgically confirmed gallbladder disease in users of OC's and estrogens. In one study, increased risk appeared after 2 years' use and doubled after 4 or 5 years' use. In one of the other studies, increased risk was apparent between 6 and 12 months' use.

7. *Carbohydrate and Lipid Metabolic Effects* — Decrease in glucose tolerance has been observed in a significant percentage of patients on OC's. For this reason, prediabetic and diabetic patients should be carefully observed while on OC's. Increases in triglycerides and total phospholipids have been observed in patients on OC's. Three studies were performed with Triphasil and no significant alterations in lipid metabolism were noted except for a slight increase in triglyceride levels in 1 study. Clinical significance of these findings remains to be defined.

8. *Elevated Blood Pressure* — Increase in blood pressure has been reported in patients on OC's. In some women, hypertension may occur within a few months of beginning OC's. In the 1st year of use, prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. Prevalence in users increases, however, with longer exposure, and in the 5th year of use is 2½ to 3 times the reported prevalence in the 1st year. Age is also strongly correlated with development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure on OC's. Hypertension that develops as a result of taking OC's usually returns to normal after discontinuing the drug.

9. *Headache* — Onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of OC's and evaluation of the cause.

10. *Bleeding Irregularities* — Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing OC's. In breakthrough bleeding, as in all cases of irregular vaginal bleeding, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or change to another OC may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase risk of thromboembolic disease. Women with past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuing OC's. Women with these preexisting problems should be advised of this possibility and encouraged to use other methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy* — Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding* — OC's given in the postpartum period may interfere with lactation and decrease quantity and quality of breast milk. Furthermore, a small fraction of the hormones in OC's has been identified in the milk of mothers on OC's; effects, if any, on the breast-fed child have not been determined. If feasible, defer OC's until infant has been weaned.

Precautions — GENERAL — 1. A complete medical and family history should be taken prior to initiation of OC's. Pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Pap smear and relevant laboratory tests. As a general rule OC's should not be prescribed for longer than 1 year without another physical examination and Pap smear. 2. Under influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while on OC's should stop OC's and use an alternate method to try to determine whether the symptom is drug-related. 4. OC's may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while on OC's. If jaundice develops, OC's should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution. 7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. Clinical significance is undetermined. 8. Serum folate levels may be depressed by OC's. Since the pregnant woman is predisposed to development of folate deficiency and incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OC's, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of OC therapy when relevant specimens are submitted. 10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OC's. a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient — See Patient Package Labeling.

Drug Interactions — Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis — See Warnings section for information on carcinogenesis.

Pregnancy — Category X. See Contraindications, Warnings.

Nursing Mothers — See Warnings.

Adverse Reactions — An increased risk of these serious adverse reactions has been associated with use of OC's (see Warnings): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies. There is evidence of an association between the following conditions and use of OC's although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients on OC's and are believed to be drug-related. Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea, amenorrhea during and after treatment, temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement, and secretion; change in weight (increase or decrease); change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening), intolerance to contact lenses. The following adverse reactions have been reported in users of OC's, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose — Serious ill effects have not been reported following acute ingestion of large doses of OC's by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration — For maximum contraceptive effectiveness, Triphasil must be taken exactly as directed and at intervals not over 24 hours. (If Triphasil is first taken later than first day of first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of use. Possibility of ovulation and conception prior to initiation of medication should be considered.)

Any time patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another contraceptive method until she has taken a tablet daily for 7 consecutive days. For full details on dosage and administration see prescribing information in package insert.

Clinical Opinion

Fertility retention in the patient with genital prolapse

David H. Nichols, MD

Providence, Rhode Island

There are several treatments from which to choose for the patient with symptomatic uterine prolapse who wishes to retain fertility. Transabdominal construction of a sacrocervical "ligament" with transplanted fascia lata femoris is a useful solution to this problem. The technique is described. (AM J OBSTET GYNECOL 1991;164:1155-8.)

Key words: Sacrocervicopexy, genital prolapse, sacrocervical ligament construction

From time to time one will see a patient with symptomatic uterine prolapse, usually parous, who wishes relief of symptoms and also wishes to retain the uterus and fertility. It is possible to assemble a spectrum of care from which a proper choice for this patient may be made.

History and diagnosis

It is important to try to establish the cause of the prolapse if possible. Usually it will be related to trauma from chronic respiratory disease, a lifestyle of heavy lifting, or previous obstetric damage. In some patients there may be a family history of genital prolapse, which suggests a congenital anomaly in the architecture of the pelvis itself, the elasticity of the patient's pelvic connective tissues, or a disturbance in the innervation of the voluntary muscles. The onset of the problem is often abrupt, the progress usually rapid, and it may be seen during the course of the previous pregnancy or immediately post partum.

The more common type of prolapse is the so-called uterovaginal or sliding prolapse that relates to damage of the connective supporting tissues of the uterus, cervix, and upper vagina. There may be a history of preexisting uterine retroversion that may coincide with a defect in the vaginal axis, which may be oriented in a more or less vertical plane. In this circumstance the cervical and vaginal portions of the cardinal and uterosacral ligament complex have become stretched, permitting these structures to sag demonstrably and progressively without coincident major damage to the pelvic and urogenital diaphragm (Fig. 1). A less common type is that represented by a general prolapse in which there is failure of all the pelvic supporting systems including those of the upper vagina as well as the urogenital and pelvic diaphragm including the levator ani. This may be of a congenital-type basis as seen in the younger age category of prolapse patients. The latter type is the more ominous prognostically because there is little in the way of gynecologic soft tissue strength to which to attach the vault of the vagina with the anticipation that it will remain there. With both types, coincident damage to the broad ligament and round ligaments will permit coincident retroversion, which stretches the ovarian ligament and usually the infundibulopelvic as well.

The patient should be examined first in the lithotomy position, where a bimanual examination will confirm the size, shape, and position of the uterus and adnexa. The patient is examined first at rest, and then during a Valsalva maneuver. Any exterior prolapse is replaced within the vagina, and without touching the patient she is asked to strain again by a Valsalva maneuver to de-

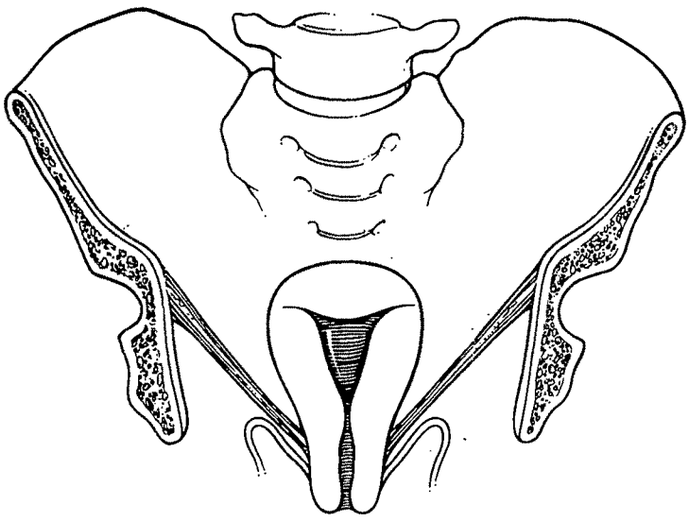

Fig. 1. Uterovaginal prolapse is shown in standing patient. Usually enterocele is present, cervix tends to be elongated, but rectocele is not necessarily present.

termine what part of the vagina appears first, as suggested by Bonney.[1] The appearance first of the vaginal vault or cervix followed by a cystocele and rectocele indicates a site of primary damage to the upper suspensory system (cardinal and uterosacral ligament complex). Initial appearance of a cystocele and rectocele followed by the cervix or vaginal vault indicates a site of primary damage to the lower supporting system (pelvic and urogenital diaphragms). This information is useful in implementing Bonney's precept: if surgical success is to be optimal, the surgeon should recognize the site of primary damage, which should be overrepaired.

The surgeon should now examine the patient's ability to contract voluntarily her pubococcygei and external anal sphincter, which will correlate to some measure with the effectiveness of innervation of these muscles by the pudendal nerve. Inability to contract them, particularly when associated with a history of rectal and urinary incontinence, strongly suggests the presence of a pudendal neuropathy. The surgeon should observe the level of the patient's perineum in relation to her glutei, inasmuch as a pudendal neuropathy is an etiologic factor for perineal prolapse. A perineal descent may indicate a major defect of the levator ani, which if symptomatic requires a separate surgical repair such as a retrorectal levatorplasty[2] or the Parks postanal repair. The presence of a rectal prolapse should be noted as an actual intussusception of the bowel. One should ask the patient to cough to determine whether there is any loss of urine. Careful inspection is made as to the support of the anterior vaginal fornix, and whether the fornix is elevated perceptably when the patient voluntarily contracts her pubococcygei, as a means of evaluating any coincident paravaginal defect.

Pelvic examination when the patient is standing (first while at rest, then when "holding" or contracting her pelvic muscles, and then when straining) will give the additional evidence of the effect of gravity on the patient's prolapse (Fig. 2). The patient is then returned to the examination table and the third pelvic examination is performed while she is in the lithotomy position and a tenaculum or long Allis clamp is applied to the posterior lip of the cervix and traction is made. By palpating the location of the cul-de-sac of Douglas and the length and strength of the uterosacral ligaments, the surgeon can identify the length of the patient's cervix. Significant elongation of both cervix and strong uterosacral ligaments suggests the more frequently seen uterovaginal or sliding prolapse, whereas a short cervix, barely perceptible uterosacral ligaments, and no enterocele suggest the less common but prognostically ominous general prolapse.

Treatment

Nonsurgical. If the pubococcygei are strong and the cervix is not elongated, one can try temporary treatment with a pessary, especially of the plastic ring-type, accompanied by a program of vigorous Kegel perineal resistive exercises (i.e., 15 voluntary squeezes six times a day). If the patient can retain the pessary she should be urged to complete her childbearing and then plan for a vaginal hysterectomy with colporrhaphy and probable McCall or New Orleans-type culdoplasty. If

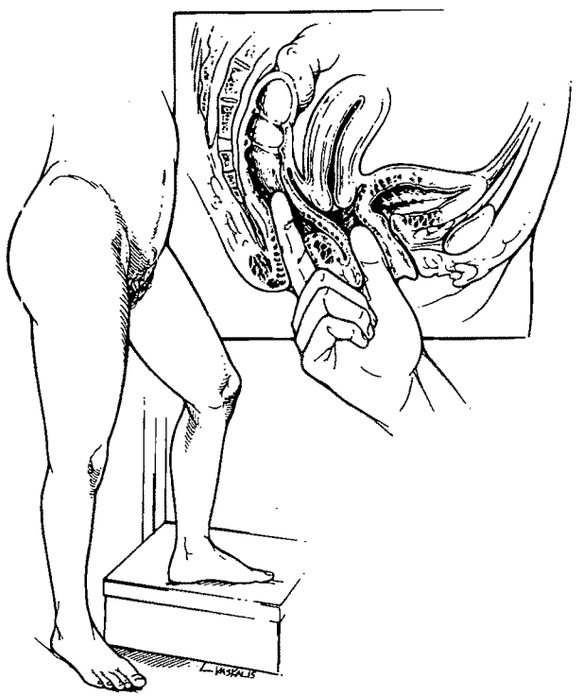

Fig. 2. Examination of patient while she is standing permits evaluation of presence or absence of prolapse of vaginal vault, extent of cystocele both at rest and when the patient strains, presence of any perineal defect, low, mid or high rectocele, and by asking patient to strain as by Valsalva maneuver, presence of palpable enterocele.

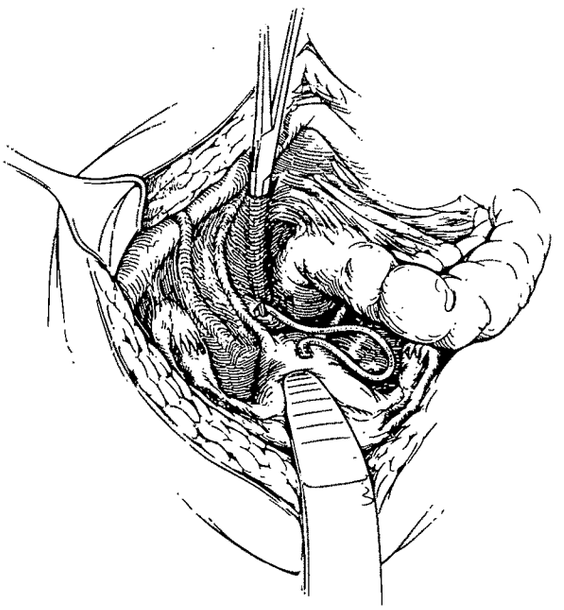

Fig. 3. Abdomen is opened, and bowel content of pelvis gently packed away and midline incision is made through peritoneum in upper third of hollow of sacrum, carefully avoiding sacral blood vessels. Retroperitoneal tunnel is established by blunt dissection from this incision beneath cul-de-sac of Douglas to site of junction of uterosacral ligaments with posterior cervix. Randall-type kidneystone forceps is useful in leading strip of fascia lata or plastic fabric through tunnel, where it is carefully fixed, first to posterior portion of cervix at its junction with uterosacral ligaments.

the pubococcygei are demonstrably weak or if the patient cannot hold a pessary, then the patient and gynecologist should consider a surgical approach to care.

Surgical

Transvaginal. If the cervix is long and there are strong but elongated cardinal and uterosacral ligaments, the patient would be a candidate for a Manchester-type repair, which includes cervical amputation, colporrhaphy, and crossing of the stumps of the cardinal and uterosacral ligaments, which are fixed to the anterior portion of the remaining cervix. Cervical amputation scrupulously avoids the internal cervix, lest a subsequent cervical incompetency be induced. Other potential disadvantages of the Manchester repair include an increased risk of premature labor, soft tissue dystocia from reduction of the size of the vagina with the colporrhaphy, and a postpartum recurrence of a cystocele and rectocele from stretching these tissues beyond their limits to elasticity.

Another transvaginal approach could be that of sacrospinous cervicopexy in which the cervix at the point to which the uterosacral ligaments are attached is sewn on one side of the pelvis to the sacrospinous ligament and coccygeus muscle complex. A nonabsorbable suture will probably be chosen, but data are lacking on the effects of subsequent pregnancy on a prolapse treated in this fashion. Williams[5] described an operation of shortening the cardinal and uterosacral ligaments for a patient without marked cervical elongation, and crossing these ligaments in front of the cervix. But this operation does not appear to be widely used.

Transabdominal surgical procedures. Construction of a sacrocervical ligament without colporrhaphy and without round ligament plication[4] is recommended for this problem. Subsequent pregnancy, labor, and delivery have been uncomplicated by the procedure and there has been no recurrence of the uterine prolapse. There should be time planned for a 6- to 8-week postoperative convalescence. Through a generous lower abdominal midline incision a retroperitoneal tunnel is established or a peritoneal incision made between the upper third of the hollow of the sacrum, beneath the cul-de-sac of Douglas, to the cervix at the point where it is attached to the uterosacral ligaments. A strap or "ligament" of fascia lata femoris is attached to these structures (Fig. 3) after the cervix is manually placed into the hollow

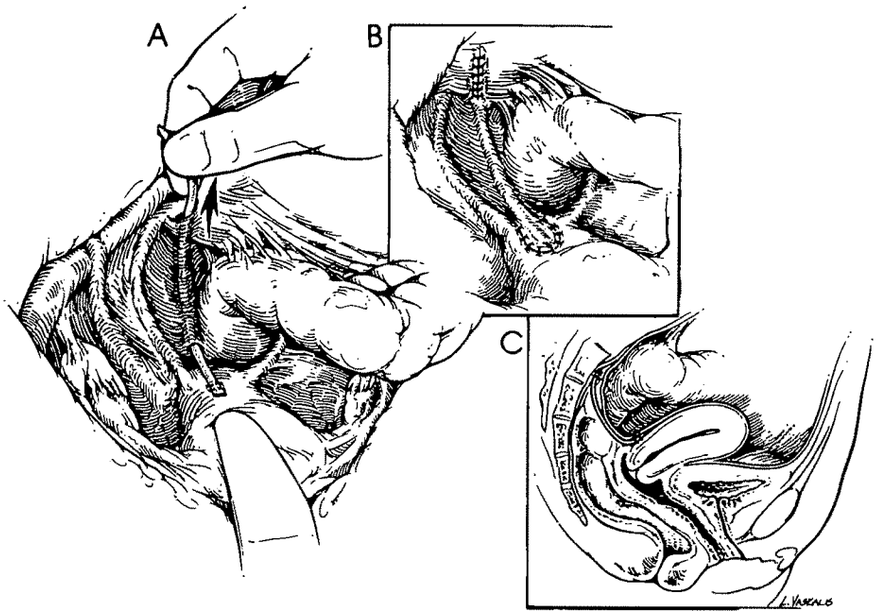

Fig. 4. A, Traction takes up some of slack in "ligament." **B**, It is fixed to periosteum of sacrum in upper third of hollow of sacrum. Some slack is made in "ligament" to permit degree of cervical mobility, and peritoneum is reapproximated from side-to-side covering new midline "ligament." **C**, End result of cervical sacropexy is shown in sagittal section. Note midline retroperitoneal ligament between posterior lip of cervix and promontory of sacrum.

of the sacrum. This will antevert the uterus. Each end of the strap is firmly sewn in place, leaving a little slack in the "ligament," and the peritoneum is reapproximated covering the ligament throughout its length (Fig. 4). By thoughtful discussion, the patient is informed preoperatively that no coincident colporrhaphy is planned, lest the vagina be made too small for future vaginal delivery and become a source of dystocia. The patient should be told that at some future date the other elements of her prolapse (cystocele, rectocele, perineal defect) will likely give evidence of progression and become the subject of a future surgical reconstruction, although by that time the patient likely will have completed her childbearing. If there is no obvious contraction of the bony pelvis, this patient should anticipate a normal vaginal delivery without recurrence of the cervical descent during the process of parturition.

The disadvantages of the operation are that the cystocele and rectocele may slowly progress in size, and if symptomatic require colporrhaphy in the future. If future hysterectomy is necessary, it may have to be performed transabdominally because of the lack of descent of the vaginal vault and cervix with traction. For the patient with symptomatic genital prolapse and urinary stress incontinence who wishes both elements to be treated with preservation of fertility, Nesbitt[5] developed a combined vaginoabdominal operation in which the paraurethral tissues of the vesical neck and the paracervical tissues of the uterine isthmus, when strong, are mobilized transvaginally, and then through a suprapubic incision are sewn to the conjoined tendon (Cooper's ligament) on each side, after any enlargement of the cul-de-sac of Douglas has been reduced by obliteration. This operation preserves a functional uterus, but to date the response to subsequent pregnancy has not been reported.

It is important to explain all treatment options to the patient, make a recommendation to her, and provide the reasons for your choice. If she agrees, supply the patient with an informed consent including the risk of recurrence and of future more complicated pelvic surgery.

The contributions of the nurse and the machine in home uterine activity monitoring systems

Ruth B. Merkatz, PhD, RN, and Irwin R. Merkatz, MD
Bronx, New York

The relative contributions of home tokodynamometry and daily nursing telephone contact to the success of preterm birth prevention programs remains a subject of debate. Because investigators have obtained conflicting data, a reinterpretation of published results was undertaken by proposing a dynamic interface between the nurse and the machine. Experience gained from the technology and the development of nursing expertise with assessment of patient symptoms are presented as interdependent factors, both of which are critical to a therapeutic nurse-patient relationship. It is proposed that this combined interactive expertise increases sensitivity to the early recognition of preterm labor. The nurse's role in providing social support to high-risk pregnant women is then identified as a potential additional independent contributing factor to reported observed reductions in preterm births. Discussion focuses on future research, public policy issues, and the need for expanding nurse-patient interactions into the home. (AM J OBSTET GYNECOL 1991;164:1159-62.)

Key words: Home uterine activity monitoring, tokodynamometry, preterm labor, preterm birth

Preterm birth prevention programs encompassing broad-based patient and professional education are considered philosophically sound from the perspective of actively involving both pregnant women and their providers in a connected system of care.[1] Recently, such efforts have been augmented for selected women who are at high risk for preterm labor by use of programs of home uterine activity monitoring with a daily telephone contact initiated by a nurse.[2,3] Although growing consensus exists with respect to the efficacy of this combined system, debate remains centered over the relative contribution of electronic monitoring versus nursing contact.[4] For example, although Iams et al.[5] achieved a statistically significant reduction in preterm birth with implementation of such a program, they could not demonstrate a difference between a subgroup of women who obtained intensive preterm labor education, had daily nursing contact, and used the monitor when compared with a group who obtained the same education and had frequent nursing contact but who practiced twice-daily uterine self-palpation. The results of this study and other similar but as yet unpublished reports have contributed to a recent ACOG (American College of Obstetricians and Gynecologists) committee opinion statement expressing reluctance to recommend home uterine activity monitoring devices for routine clinical use.[6] The ACOG committee concluded that further prospective controlled studies must still precede public policy decisions with respect to widespread implementation. Nevertheless, it is our opinion that important insights can be gained from a reinterpretation of already published results. We propose a theoretical dynamic interface among nurse, machine, and patient as one means of reconciling previously conflicting reports.

The nursing component in clinical studies of home uterine activity monitoring

The results of the Iams study have been interpreted to suggest that the home uterine activity monitoring failed to independently add value to the nurse-initiated telephone contact.[5] Several relevant questions exist with respect to the influence of the study's design on this conclusion. Most important, the authors themselves suggest the possibility of a Hawthorne effect; i.e., that the knowledge that a study was being conducted was, in itself, a factor that created change. This issue was raised because the same nurses cared for both groups of pregnant women enrolled in the study. The design created an opportunity for both the monitored women and the control women to respond in accordance with similar nursing expectations. It also increased the nurses' sensitivity toward recognition of patients' signs and symptoms of early preterm labor, regardless of whether a monitor was used. From a theoretical nursing perspective, it may be assumed that the critical thera-

peutic relationship between patient and nurse was established without respect to group assignment.

The value of a growing clinical expertise gained by participating nurses over the 2½ years of the study is an important factor in consideration of the extent of the Hawthorne effect. This consideration may help to explain how women in the Iams study who did not use the uterine monitor were also able to achieve important reductions in preterm births.[5] A parallel illustration that is related to the development of skills and expertise is provided by the Dreyfus Model of Skill Acquisition.[7] This model has been used to explain how pilots develop the knowledge necessary to safely guide their planes. The expert pilot, in contrast to the novice pilot, makes decisions that are based on a transformation of knowledge rather than the application of the fixed rules used during learning stages. With experience, the expert pilot is able to deviate in the manner in which he or she utilizes the information displayed on the plane's video panel. A similar opportunity exists for nurses who work with women at risk for preterm birth and who use the home uterine activity monitoring systems. The nurses interpret uterine monitoring strips on a regular basis over an extended period of time and then discuss their findings about specific symptoms with the respective patients. These nurses progressively gain an expertise that enables them to extrapolate these daily experiences to other related clinical situations. They become increasingly skilled in deciphering their patients' reports of symptoms without depending as much on viewing transmitted uterine activity strips. Thus in Iams' study it can be suggested that nursing expertise in combination with technology served as an important method of assessing women in both subgroups of patients and that this expertise may well have served as a confounding variable. It is also plausible to assume that the nurses' recognition of the clinical signs and symptoms of preterm labor in both groups of pregnant women also improved over time. This possibility may provide the needed explanation for the observed decline in preterm births evidenced for all women during the second year of the investigation. It appears that the two groups of subjects ultimately may have been exposed to the same clinical nursing intervention that improved progressively as a result of a growing expertise among the nurses. The technology, on the other hand, was fundamental in contributing to the development of this nursing expertise.

A study reported by Morrison et al.[3] did result in a lower preterm delivery rate among pregnant women who were monitored, when compared with control women who used uterine self-palpation. In this instance, however, the same group of nurses was not involved in both arms of the investigation, and expert nursing skills specific to recognizing uterine activity were probably not applied uniformly to all subjects (Morrison JC. Personal communication, December, 1989). As a result, an "independent" contribution of the monitoring system may have been able to surface to the extent that these investigators could have achieved statistically significant outcome differences between the two groups of subjects. Their finding of a significantly earlier identification of preterm labor in the monitored group is consistent with such an assumption. The authors were able to conclude that objective information obtained from home uterine activity monitoring did indeed augment the nursing contribution in reducing preterm deliveries in a monitored group of patients.

The nurse-patient relationship in association with uterine monitoring systems

The issue of using uterine self-palpation as a control in both the Iams and Morrison studies raises additional theoretical questions with respect to the nurse-patient-physician relationship.[3, 5] The practicality and validity of self-palpation for the presence of uterine activity associated with early preterm labor has recently been challenged. Newman et al.[8] showed that patient perception of uterine activity failed to yield consistent, reliable information. Brustman et al.[9] confirmed this finding and demonstrated a lack of improvement with intensive nursing educational support. These investigators have hypothesized a physiologic explanation for the attenuated perception of preterm uterine activity. If such a phenomenon is indeed operative, it would appear that asking women to engage in twice-daily uterine self-palpation has inherent potential problems. When women are asked by their providers of care to participate in time-consuming health-related activities for which there is minimal benefit, they may ultimately discontinue the prescribed regimen. Both the nurse-patient relationship and the physician-patient relationship will thereby be threatened. This notion is supported by a finding in the Iams study of a significantly higher drop-out rate among those women who used uterine self-palpation when compared with those who used electronic monitoring (21% vs 10.2%).

Requesting women to invest their time in self-monitoring of uterine activity raises an important issue of patient "honesty" associated with the reporting process. Experience documented with patient self-reporting of blood glucose values suggests that this issue also has the potential to exert a negative influence on the critical therapeutic relationships between providers and patients. Traditional logbook reporting of blood glucose values by both pregnant and nonpregnant diabetic patients proved to be unreliable when validated by a memory-based glucometer system.[10] "Phantom" values that were substituted for testing

omissions and were lower than actual blood glucose values were common patterns in patients' logbook recordings. A significant improvement was achieved only after the patients were informed about the memory chip in the glucometer and were made aware that the true glucose values were retrievable. Physicians, diabetic nurse educators, and their patients could then work together to achieve better glucose control on the basis of real data and an improved relationship of mutual trust. The potential analogy with the two choices of method for patient monitoring of preterm labor is striking. The technique of uterine self-palpation may be difficult to perform because perception of preterm uterine activity that occurs before actual labor may be attenuated. Contractions are usually painless and often can be difficult to distinguish from fetal movements. Furthermore, the mother receives no external verification of her perceptions. In contrast, when a monitor is utilized, the patient receives both feedback and positive reinforcement on a more objective basis. Although her perceptions may or may not be verified by the tracing, the feedback received may help her to distinguish contractions from other sensations. In addition, decisions regarding activity, medications, or the need for physician notification can be jointly determined by the patient and the nurse. Thus the total onus for accurate identification of early preterm labor is no longer the sole responsibility of the pregnant woman.

It could be argued, on the other hand, that the electronic monitoring system forces the mother to become unduly dependent on the nurse for feedback and reinforcement. A system of home uterine activity monitoring that allows pregnant women to see their own recordings at home provides a potential solution to this theoretical problem. This approach offers women the opportunity to improve their own skills and to verify perceptions while maintaining important contact with the nurse. The nurse-patient relationship can ultimately be strengthened by such an interactive system.

Social support provided by the nurse and its influence on preterm labor

It has been estimated that as much as 40% of low birth weight can be traced to environmental and psychosocial factors.[11] In this context, an additional explanation for the more favorable outcomes achieved by most home monitoring initiatives is the contribution of increased social support provided by the nurses. It has been hypothesized that patient stress and anxiety are important underlying variables in preterm labor and that stress and anxiety are presumably mediated by catecholamine release, changes in uterine blood flow, or other physiologic processes. It has been suggested that in pregnancy, as in other health-related situations, perceived social support can serve to buffer the adverse physiologic effects of stress.[11-14] Social support may also exert a positive influence on the pregnant woman's own health-seeking behaviors.[13-15] The provision of added social support in pregnancy has therefore been considered a strategic intervention in reducing the incidence of prematurity.[13, 15]

To date, attempts to augment social support for improving perinatal outcome have yielded conflicting results. In the United States, programs by Heins et al.[15] and Olds et al.[16] have resulted in significant reductions in preterm birth. These two initiatives have focused on providing social support to low-socioeconomic, pregnant teenagers via either specially trained "resource mothers" or nurses who make home visits. On the other hand, Spencer et al.,[17] in Manchester, England, did not achieve similar benefits by using "family workers" to visit low-income women who were also at high risk for preterm birth. These investigators acknowledge that a high incidence of "refusers" after randomization may have affected their study negatively. The fact that 58.7% of the women in their experimental group chose not to accept home visitation underscores the importance of carefully structuring interventions to suit the specific needs of targeted women. The majority of refusers in the Manchester study claimed that they already had adequate social support. A current model suggests that social support is an interactive process in which the recipient must play an active role.[18] In such a theoretical model the pregnant woman must not only desire the intervention but she must not be made to feel threatened by its potential intrusiveness.

Although there is no consistent definition of social support, most investigators concur that it generally includes interactions that provide recipients with a sense of security, a reassurance of self-worth, and an opportunity to obtain valued objective information.[18] Daily telephone contact between a knowledgeable nurse and the patient at risk for preterm birth may facilitate such interactions. Such contact represents a relatively nonintrusive means of providing support while focusing primarily on patient-driven specific issues. It may be presumed therefore that such support was provided to the largely middle-class sample of women who constituted Iams' study group and that this type of support could have contributed to favorable outcomes in these patients. An opportunity for the pregnant woman to converse daily with a concerned provider is difficult to achieve in traditional private-practice settings. Patients are typically reluctant to make repeated telephone calls for fear of imposing excessively on a busy office staff.

Future research issues

Preterm birth disproportionately affects poor, minority women who are primarily cared for in clinic settings.[11, 19] For such women social disorganization and

hostile environmental conditions often create unusually stressful life circumstances. Theoretically, these women should also benefit from the focused social support embodied in the home uterine activity monitoring systems and from the expertise of the nurses. Studies of efficacy in this high-risk group have been limited, however, because of access to care and other public policy issues. Even access to telephones may represent a limiting factor for this research. The study of Morrison et al.[3] is of particular importance because of its demonstrated benefits in the early diagnosis of preterm labor among black women in rural Mississippi. A more recent collaborative trial from four tertiary centers, including two with a large population of indigent black women, provides similar encouraging findings.[20] Future studies concentrating on efficacy questions among different groups of high-risk women are clearly indicated. Such studies must be afforded a fair priority status vis-à-vis the multiple competing demands for limited resources.

Future prematurity prevention initiatives incorporating home uterine activity monitoring or other technologic interventions should also stress the importance of including periodic face-to-face contacts between patient and nurse. One potential criticism of machine-driven forms of nursing practice has been a concern that the nurse might become too technologically dependent and might lose her holistic orientation.[21] Home visitation to pregnant women is a strategy that is used widely in other Western countries but remains uncommon in the United States. Research with respect to monitoring uterine activity should be broadened to include this perspective. These comprehensive programs have the potential to further our growing national commitment toward providing improved care for pregnant women. Physicians and nurses must continue to exert a leadership influence through their interdisciplinary collaborations.

Bleeding patterns during continuous combined estrogen-progestogen therapy

Ulla Marslew, MD, Bente J. Riis, MD, and Claus Christiansen, MD
Glostrup, Denmark

Bleeding and climacteric symptoms were recorded in two groups of postmenopausal women receiving either continuous combined estradiol and norethisterone acetate or estradiol and cyproterone acetate. Out of a sample of 99 postmenopausal women aged 45 to 54 years, 86 completed a 2-year, double-blind, placebo-controlled study. Comparison of the bleeding patterns in the two groups revealed a statistically significant difference: More women in the estradiol–cyproterone acetate group experienced bleeding and for a longer duration. Thirteen women in the estradiol–norethisterone acetate group were amenorrheic, compared with two in the other group. The Kupperman index score in both groups declined to about 30% to 40% of initial values ($p < 0.001$). The hot flushes in both treatment groups decreased to a highly significant degree ($p < 0.001$), to a value below 20% of baseline values. We conclude that a continuous combination of estrogen and progestogen can produce amenorrhea and symptomatic relief. However, the progestogen components seem to differ in their ability to control bleeding. (Am J Obstet Gynecol 1991;164:1163-8.)

Key words: Continuous estrogen-progestogen, bleeding pattern, climacteric symptoms

Postmenopausal hormone replacement therapy is widely prescribed to alleviate postmenopausal symptoms and to prevent osteoporosis.[1, 2] For women with an intact uterus, the hormone replacement therapy should consist of estrogen combined with a progestogen to eliminate the increased risk of endometrial hyperplasia and cancer.[3, 4] To imitate the normal menstrual cycle, the progestogen is generally added sequentially. However, this therapy has the major disadvantage of inducing bleeding.

Continuous combined estrogen-progestogen therapy was introduced to overcome the problem, the philosophy being that continuous progestogen administration would provide a continuous inhibition of the estrogenic action and thereby keep the endometrium atrophic. The risk of hyperplasia would thus be eliminated and women would be spared the inconvenience of bleeding.

The aim of this 2-year, double-blind, placebo-controlled study was to compare the bleeding pattern during two continuous combined regimens. The changes in menopausal symptoms were also recorded and compared.

Material and methods

The participants were recruited in 1983[5, 6] and 1988.[7] Ninety-nine women aged 45 to 54 years were selected by postmenopausal age (6 months to 3 years) and freedom from past and present diseases and medications known to influence the variables studied or to contraindicate the medication used in the trial. Further details of the selection procedure are given elsewhere.[5, 7] After the initial examination the women were randomly allocated to two groups. Group 1 received continuous estradiol–norethisterone acetate (2 mg of 17β-estradiol and 1 mg of norethisterone acetate) ($n = 24$) or placebo tablets that were identical in appearance ($n = 25$).[5, 6] Group 2 received continuous estradiol–cyproterone acetate (2 mg of estradiol valerate and 1 mg of cyproterone acetate) ($n = 25$) or placebo tablets that were identical in appearance ($n = 25$).[7]

All women gave informed consent (Helsinki Declaration II) and the trials were approved by the Copenhagen County Ethical Committee. The women were treated for 2 years with an examination done every 3 months.

Table I. Clinical data and initial values of serum estradiol in pooled treatment and placebo groups (mean ± SEM)

	No.	*Age (yr)*	*Postmenopausal age (mo)*	*Height (cm)*	*Weight (kg)*	*Kupperman index**	*Serum estradiol† (nmol/L)*

Estradiol-cyproterone acetate	43	50.8 ± 0.3	19.3 ± 1.4	164 ± 1	65.7 ± 1.5	11 (4-29)	0.087 (0.077-0.098)

*Mean and range.
†Geometric mean.
‡$p < 0.01$.

Between 21 and 24 months of therapy the women in group 2 and the corresponding placebo group had an endometrial biopsy taken, and therefore the bleeding records of both groups at 24 months were not included in the calculations.

Compliance. Of the 49 women in group 1, 43 (88%) completed the 24-month study. Three women left the hormone group—one because of persistent uterine bleeding and two because of lack of time. Three women left the placebo group—two because of major climacteric symptoms and one because of edema of the legs and fingers. Thus 21 women remained in the hormone group and 22 in the placebo group of group 1.

Of the 50 women in group 2, 43 (86%) completed the 24-month study. Six women left the hormone group—three because of persistent uterine bleeding, two because of lack of time, and one because of edema of the legs. One woman left the placebo group because of the development of thyrotoxicosis. Thus 19 women remained in the hormone group and 24 in the placebo group of group 2.

Record of bleeding pattern. At baseline the women were shown how to record bleeding on a calendar. Each day there were asked to note down the days in which they experienced bleeding, defined as reddish vaginal discharge necessitating use of pads. At each examination done every 3 months, the women returned the completed calendar to the department and received a new one for the next 3 months.

Record of menopausal symptoms. At baseline the women were shown how to record clinical symptoms on a questionnaire, which they filled in every 3 months. The questionnaire covered the 11 symptoms on the menopausal index of Kupperman et al.[8]: hot flushes (with and without sweating), paresthesias, insomnia, nervousness, melancholia, vertigo, fatigue, arthralgias or myalgias, headache, palpitations, and formications. Each symptom on the Kupperman index was rated on a scale from 0 to 3 for no, slight, moderate, and severe complaints. To calculate the Kupperman index, the symptoms were weighted as follows: hot flushes (×4), paresthesias (×2), insomnia (×2), nervousness, (×2), and all other symptoms (×1). The highest potential score is thus 51.

Each woman was carefully instructed on how to record episodes of bleeding on a calendar and how to fill in a questionnaire on menopausal symptoms. A doctor was available to help with the questionnaire. Returned questionnaires were examined for errors.

Serum estradiol measurements. The serum concentrations of estradiol were measured every 6 months with antiserum supplied by BioMarkor, and standards were prepared with estradiol supplied by Sigma. The intraassay and interassay variations were 4% and 14%, respectively, and the sensitivity was 0.010 nmol/L.

Statistical analysis. Student's *t* test for unpaired data was used to test the significance of differences in all the initial values (Table I), except the initial Kupperman index, which was tested by Wilcoxon's test for unpaired data.

The pretreatment values of the menopausal index and the hot flushes for each subject were assigned a value of 100%, and subsequent measurements were expressed as percentages of the value. To eliminate the genuine climacteric complaints also experienced by premenopausal women,[9] women with an initial Kupperman index score of <4 were not included in the calculations of the Kupperman index. Student's *t* test for paired data was used to test the significance of differences within the groups and the *t* test for unpaired data was used to test the significance of differences between the groups.

The frequency of bleeding during each 3-month period was calculated as the number of women who experienced bleeding, irrespective of the number of episodes (each woman was counted only once). The average duration (days) in each 3-month period was calculated as the sum of the days on which bleeding occurred divided by the number of women who experienced it in this period. Fisher's exact test was used to test the significance of differences between the groups.

Changes in the serum concentration of estradiol were

Pattern of bleeding, expressed as number of women with episodes in each 3-month period—treatment with estradiol–norethisterone acetate. *Open bars* represent women with bleeding. *Hatched* and *closed bars* represent women without bleeding. *Number* or *letter* in *open bars* identifies woman. *NS,* Not significant; *asterisk,* $p = 0.05$; *double asterisk,* $p < 0.01$; these values represent difference between estradiol–norethisterone acetate and estradiol–cyproterone acetate groups.

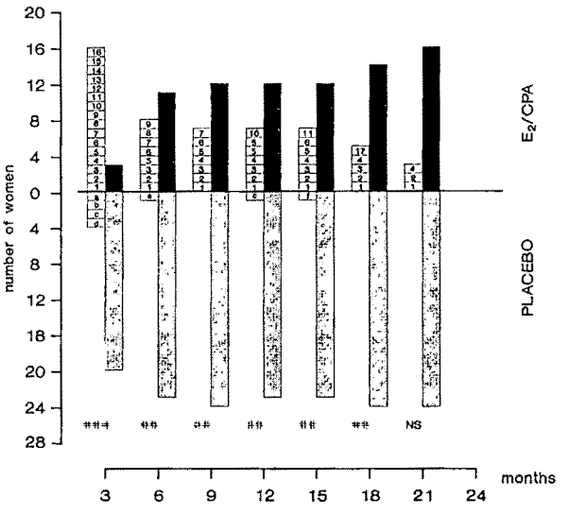

Fig. 2. Pattern of bleeding, expressed as number of women with episodes in each 3-month period—treatment with estradiol–cyproterone acetate. *Open bars* represent women with bleeding. *Hatched* and *closed bars* represent women without bleeding. *Number* or *letter* in *open bars* identifies woman. *NS,* Not significant; *double number sign,* $p < 0.01$; *triple number sign,* $p < 0.001$; these values represent difference between estradiol–cyproterone acetate group and corresponding placebo group.

calculated by the geometric mean, because of a non-normal distribution of the data.

Results

Table I gives the clinical data and the initial values of serum estradiol in the two groups of women. Group 1 women had a slightly higher postmenopausal age ($p < 0.01$).

Fig. 1 shows the pattern of bleeding in group 1. In the first 3 months bleeding occurred in seven women receiving estradiol–norethisterone acetate for an average duration of 10 days. In the next 3 months the number of women in the estradiol–norethisterone acetate group with bleeding had decreased to five, with average bleeding duration remaining at 10 days. Four of the women were among the seven with episodes in the first period, whereas one woman first experienced bleeding in the second period. After the first 6 months one woman in the hormone group experienced one further episode of bleeding (10 days). None of the women in the placebo group had bleeding.

Fig. 2 shows the pattern of bleeding in group 2 treated with estradiol–cyproterone acetate or placebo. In the first 3 months bleeding occurred in 16 women in the hormone group for an average duration of 10 days and in four women in the placebo group for an average of 7 days. In the next 3 months the number of women in the hormone group had decreased to eight, with an average duration of 15 days, and one woman in the placebo group had bleeding for 7 days. In the next three periods (15 months of treatment in all) the number of women in the hormone group with bleeding was constantly 7; the duration ranged from 7 to 10 days. Two women in the placebo group had bleeding episodes in the fourth and fifth periods, each lasting 5 days. A number of women treated with estradiol–cyproterone acetate also had bleeding in periods six and seven. As the figure shows, the same women in the hormone group tended to have repeated episodes.

The data summarized in Table II give the number of women who experienced bleeding and the average duration (days) in 3-month periods for 21 months of therapy. The number of women who dropped out of the study because of persistent uterine bleeding are also listed. The women in the estradiol–cyproterone acetate group had more bleeding episodes than those in the estradiol–norethisterone acetate group. This was statistically significant ($p < 0.01$ to 0.05). In the estradiol–norethisterone acetate group 13 women were amenorrheic throughout the study, each of four women had one episode of bleeding, three women had two episodes, and one woman had three episodes. In the estradiol–cyproterone acetate group two women were amenorrheic, each of six women had one episode of

bleeding, four women had two episodes, one woman had three, three women had five, one woman had six, and two women had seven episodes.

Fig. 3 shows the Kupperman index score for the 11 symptoms described in the Material and methods section. In both hormone groups the score declined to a highly significant degree during the first 3 months of treatment, by 60% and 70% of the initial values, respectively ($p < 0.001$). Both placebo groups had unchanged values.

Fig. 4 shows the hot flushes as an isolated symptom in the four groups of women. In both hormone groups the hot flushes decreased to a highly significant degree, to a value <20% of baseline ($p < 0.001$). There were no significant differences in response between the two treatment groups. The placebo groups had unchanged values.

Comment

The populations in this study were recruited in 1983 (estradiol–norethisterone acetate group) and 1988 (estradiol–cyproterone acetate group) by the same selection procedure. A questionnaire was mailed to a very large number of women, aged 45 to 54 years, living in the "catchment" area of Glostrup Hospital. This population has been shown to be representative of Danish middle-aged women.[10] The frequency of response was above 80% and our study samples may therefore be considered representative of healthy postmenopausal women.

The study design ensured a double-blind procedure and the women were examined at 3-month intervals. This afforded a continuity in the data sampling.

The estradiol–norethisterone acetate group initially had a 6-month higher postmenopausal age than the estradiol–cyproterone acetate group ($p < 0.01$). This otherwise confounding factor was corrected for by the longitudinal design.

Compliance was above 85% and, although more women in the estradiol–cyproterone acetate group left the study than in the other groups, the number ($n = 19$) completing it was still acceptable. One woman in the estradiol–norethisterone acetate group and three women in the estradiol–cyproterone acetate group left the study because of persistent uterine bleeding.

It has been suggested[11, 12] that hormone replacement therapy decreases the risk of cardiovascular diseases in postmenopausal women. Progestogens counteract the estrogenic effect on serum lipids and lipoproteins; this may be especially marked for those derived from testosterone, such as norethisterone acetate.[13, 14] Hydroxyprogesterone derivatives, such as cyproterone acetate, may possess this effect on the lipids to a lesser extent.[13-16] New combinations of estrogen and progestogen, including hydroxyprogesterone derivatives, are thus being intensively studied.

A major concern with regard to postmenopausal estrogen therapy is the risk of endometrial hyperplasia and carcinoma.[17, 18] Histologic studies[19, 20] indicate that the addition of a progestogen may minimize the risk, and this has been confirmed by a recent prospective epidemiologic study.[4] The sequential addition of a progestogen produces regular bleeding in most women, which is a major disadvantage,[21] and therapy with a continuous combination of estrogen and progestogen was introduced to overcome the problem.[22] The achievement of endometrial atrophy over time requires a delicate balance between the estrogenic and progestogenic activities on the endometrium. The hormonal effect depends on the dose, rate of absorption, and half-life of the particular estrogen and progestogen; therefore the difficulty in achieving this balance is obvious.

Earlier studies[23, 24] of a continuous combination of estradiol and norethisterone acetate have demonstrated a significantly lower bleeding frequency than

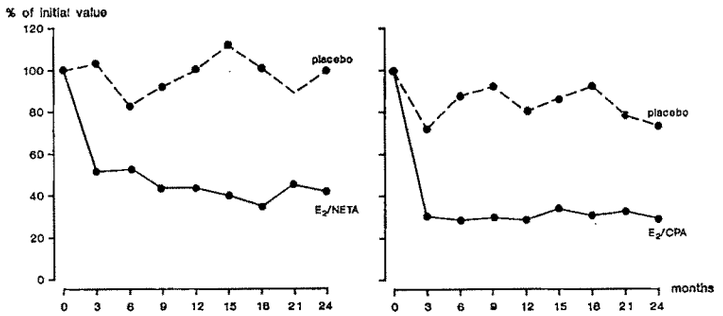

Fig. 3. Mean percentages for Kupperman index during 2 years of therapy with two continuous estrogen-progestogen treatments.

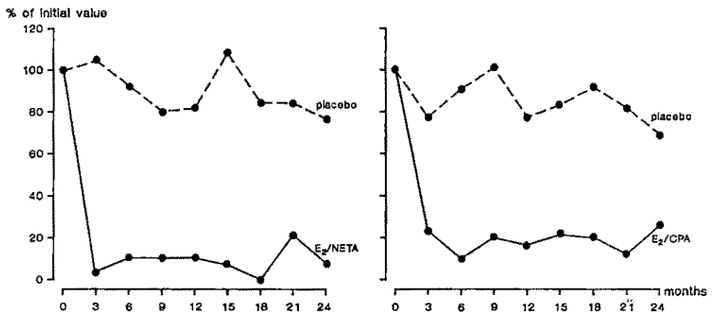

Fig. 4. Mean percentages for hot flushes (Kupperman index) during 2 years of therapy with two continuous estrogen-progestogen treatments.

that occurring with sequential hormone replacement therapy, but both studies report that a number of women (15% and 35%, respectively) experienced irregular bleeding in the first 3 months of therapy, a finding that is consistent with our results. After 3 months the frequency decreased significantly and as in our study bleeding finally stopped. In their study of four continuous estrogen-progestogen combinations (2 mg of estradiol plus 1 or 0.5 mg of norethisterone acetate or 2 mg of estradiol plus 5 or 2.5 mg of megestrol acetate), Sporrong et al.[25] concluded that a continuous combination of estradiol and progestogen can be used for long-term treatment of climacteric complaints in postmenopausal women and that after 4 months clinical efficacy of the progestogens is the same, irrespective of the type and dose administered. Their study also revealed substantially less bleeding with the formulation containing 1 mg of norethisterone acetate, whereas they had approximately the same percentage of amenorrheic women as we had in our estradiol–norethisterone acetate group and the average number of days with bleeding in their study was lower than in ours. The explanation may be that their study population was about 5 years older and thus had a correspondingly higher postmenopausal age. This may decrease the frequency of bleeding during continuous combined hormone replacement therapy, as indicated by a study from our group[26] in which 65-year-old women were given the same estradiol–norethisterone acetate combination. Bleeding was almost negligible in these women. Furthermore, the study of Hövik et al.[27] showed that when postmenopausal women were treated with continuous estradiol–norethisterone acetate immediately after sequential treatment with the same compound, the bleeding frequency was increased.

The pattern of bleeding in the estradiol–cyproterone acetate group was different from that in the estradiol–norethisterone acetate group. Significantly more women experienced bleeding during the first 6 months, and irregular bleeding continued in a substantial number of women thereafter, although it tended to decrease. This indicates that, with regard to the control of bleeding, the estrogen-progestogen balance in the estradiol–cyproterone acetate combination was inferior to that in the estradiol–norethisterone acetate combination. The half-life of norethisterone acetate is thus about 10 times lower than that of cyproterone acetate (mean ± SD, 4.2 ± 1.8 and 38 ± 14, respectively), a distinct difference because of the high affinity of cyproterone acetate to fatty tissue. This may influence the control of bleeding. On the other hand, bleeding in the estradiol–cyproterone acetate group did not result

from hyperplasia, because no endometrial biopsy specimens showed proliferation.

We conclude that a continuous estrogen-progestogen combination induces amenorrhea and affords symptomatic relief. However, the progestogens seem to differ in their interaction with estrogen to bring bleeding under control.

We thank Novo Industri A/S and Schering for supplying the hormone and placebo preparations.

Effect of low-dose aspirin on vascular refractoriness in angiotensin-sensitive primigravid women

Henk C.S. Wallenburg, MD, PhD, Guus A. Dekker, MD, PhD, Jolande W. Makovitz, MD, and Nel Rotmans, BSc

Rotterdam, The Netherlands

The hypothesis that an enhanced vasopressor response to angiotensin II in pregnancy may be corrected by suppressing production of platelet thromboxane A_2 with low-dose aspirin was tested in a randomized, placebo-controlled, double-blind trial. We studied 36 normotensive primigravid women with an elevated blood pressure response to intravenously infused angiotensin II at 28 weeks' gestation; 18 women received 60 mg of aspirin daily and the same number received matched placebo until 34 weeks' gestation, when angiotensin-sensitivity was again determined. In women taking aspirin, values of thrombin-induced platelet malondialdehyde production were approximately 10% of those determined in the placebo group, indicating marked suppression of thromboxane A_2 synthesis. In the aspirin group vascular refractoriness to angiotensin II was restored in 14 of 17 treated women, by comparison with 5 of 15 women in the placebo group who had remained normotensive. These results support the hypothesis that prostacyclin/thromboxane imbalance is an important pathophysiologic factor in the development of the enhanced angiotensin-sensitivity associated with pregnancy-induced hypertensive disorders. (AM J OBSTET GYNECOL 1991;164:1169-73.)

Key words: Angiotensin II, pressor response, low-dose aspirin, prostaglandins

Pregnancy is associated with profound physiologic alterations in vascular behavior, including vasodilatation and a marked refractoriness to the vasopressor effect of intravenously infused angiotensin II.[1] The vascular adaptations to pregnancy are thought to depend to a large extent on delicate changes in eicosanoid biosynthesis, in particular involving prostacyclin and thromboxane A_2. There is increasing evidence that in normal pregnancy these changes lead to a dominance of the biologic effects of prostacyclin, a potent vasodilator and inhibitor of platelet aggregation produced by vascular endothelium and placenta, over the opposing effects of thromboxane A_2, a potent vasoconstrictor and stimulator of platelet aggregation, mainly produced by platelets.[1, 2]

For reasons that are not yet well understood, prostacyclin synthesis may be insufficient in some, primarily primigravid, women, and the prostacyclin-thromboxane A_2 balance may become tilted in favor of thromboxane A_2,[1-3] thus leading to the vasoconstriction and platelet activation characteristic of pregnancy-induced hypertensive disorders.[4-6] Enhanced sensitivity to the vasopressor effect of infused angiotensin II can be demonstrated long before the clinical manifestation of high blood pressure[7] and has been postulated as an important pathophysiologic mechanism in the development of pregnancy-induced hypertensive disorders and an early, if not the first, sign of a prostacyclin-thromboxane A_2 imbalance.[1, 8] We have shown that a daily dose of 60 mg aspirin (acetylsalicylic acid) prevents the development of preeclampsia in primigravid women with enhanced angiotensin-sensitivity at 28 weeks' gestation,[9] probably through selective inhibition of platelet cyclooxygenase and synthesis of thromboxane A_2, resulting in correction of an imbalance between the biologic effects of prostacyclin and thromboxane A_2.[10, 11] If enhanced angiotensin sensitivity is indeed a pathophysiologic factor in the development of pregnancy-induced hypertensive disorders caused by prostacyclin-thromboxane A_2 imbalance, low-dose aspirin would also be expected to restore, or at least improve, refractoriness to the pressor effects of angiotensin II in angiotensin-sensitive pregnant women. To test this hypothesis we conducted a randomized, placebo-controlled, double-blind trial to investigate whether a low dose of aspirin, taken daily from 28 to 34 weeks' gestation, would reduce the vasopressor response to intravenously infused angiotensin II in normotensive, angiotensin-sensitive primigravid women.

Material and methods

The trial was designed to include 36 angiotensin II-sensitive primigravid women in the early third trimester of pregnancy, 18 in the treatment group and 18 in

the placebo group. We chose this number to demonstrate statistical significance with an α-error and a β-error of 0.05, assuming the possibility to restore angiotensin-refractoriness in 85% of treated and in 40% of untreated women. The assumptions were based on the results of our previous trial with low-dose aspirin,[9] on the premise that pregnancy-induced hypertensive disorders and angiotensin II sensitivity are different manifestations of the same pathophysiologic disturbance. The end point of the study was the blood pressure response to infused angiotensin II following 6 weeks of active or placebo treatment.

To recruit the required number of angiotensin-sensitive pregnant women, healthy primigravid women with an uncomplicated pregnancy of 26 weeks' duration attending the Antenatal Clinic of the University Hospital Rotterdam-Dijkzigt were given written and oral information about the study protocol as approved by the Hospital and University Ethics Committee.

Angiotensin sensitivity test. The blood pressure response to intravenously infused angiotensin II was determined at 28 weeks' gestation in 142 women who gave informed oral consent. None of the women had a history of hypertension or cardiovascular or renal disease. The course of pregnancy had been uncomplicated in all cases, with a maximum diastolic blood pressure of ≤85 mm Hg; none of the women used any drugs except oral iron supplements, and diets were unrestricted.

The angiotensin II sensitivity test was performed as described previously.[9, 12] Briefly, an intravenous catheter was introduced into the right cubital vein for administration of angiotensin II–amide (Hypertensin, Ciba Geigy, Arnhem, The Netherlands) in 5% dextrose by means of an infusion pump. Blood pressure was measured every 3 to 5 minutes in the left upper arm with a standard mercury sphygmomanometer with the women in the left lateral recumbent position. The point of muffling of the Korotkoff sounds (phase IV) was recorded as the diastolic pressure. After a stable blood pressure and heart rate had been recorded for at least 15 minutes, infusion of angiotensin II was started at a rate of 3 ng/kg/min and increased stepwise by 1 ng/kg/min at 5-minute intervals. Three blood pressures were taken at the end of each incremental dose, and the median values were recorded. The minimum amount of angiotensin II (per kilogram per minute), which caused a rise in diastolic blood pressure of 20 mm Hg above the mean diastolic blood pressure level before the start of the infusion, was defined as the effective pressor dose.

The test was stopped after the effective pressor dose had been determined in triplicate or when infusion of 12 ng/kg/min had not caused a rise in diastolic blood pressure of 20 mm Hg. A positive angiotensin II sensitivity test was defined as a test with a median effective pressor dose of 10 ng/kg/min or less.[12] All tests were carried out by one of us (J.W.M.).

Study protocol. The 36 women with a positive angiotensin II sensitivity test were enrolled in the study at 28 weeks' gestation, immediately after the test. Each woman received a coded package with 50 tablets containing 60 mg of aspirin or matched placebo, according to a randomization list. The women were instructed to take one tablet daily at breakfast over a 6-week period, until angiotensin sensitivity was again tested; at each antenatal visit they were asked how many tablets remained. The women were asked to report the use of any other drugs and were explicitly told not to use aspirin. All women involved in the study received standard antenatal care, in which the investigators were not involved.

Angiotensin sensitivity was again determined at 34 weeks' gestation in all women who had remained normotensive (diastolic blood pressure ≤85 mm Hg); the same procedure applied at 28 weeks' pregnancy was used. After the introduction of the venous catheter, a blood sample was drawn for determination of the thrombin-induced production of malondialdehyde by platelets. Malondialdehyde is a stable by-product of platelet thromboxane synthesis[13]; its thrombin-induced production is approximately 5 nmol/10^9 platelets in the third trimester of uncomplicated pregnancy.[5] Daily ingestion of 60 mg of aspirin causes about 90% inhibition of platelet malondialdehyde synthesis,[9] which can thus be used as a sensitive index of the use of aspirin. The investigators remained unaware of the results until the end of the study when the code was broken.

The study was terminated after the second angiotensin II sensitivity test at 34 weeks' gestation. Some of the women then started taking 60 mg aspirin in an attempt to reduce the risk of developing pregnancy-induced hypertensive disorders.[9]

Statistical analysis. Differences in relative frequencies between placebo and treatment groups were analyzed with the use of Fisher's exact test. The Wilcoxon test for paired and unpaired data was used as appropriate to analyze differences in continuous variables between the two groups. A probability value of <0.05 was considered significant. Where appropriate, 95% confidence intervals were calculated.

Results

At the beginning of the study the two groups were comparable with regard to age, body weight, baseline blood pressure, and heart rate (Table I). In the aspirin

Table I. Clinical characteristics of 36 angiotensin II–sensitive primigravid women at 28 weeks' gestation

	Aspirin (n = 18)		*Placebo (n = 18)*	
	Median	*Range*	*Median*	*Range*
Age (yr)	23	18-36	24	19-34
Weight (kg)	73	55-96	72	46-88
Systolic blood pressure (mm Hg)	115	103-136	111	100-128
Diastolic blood pressure (mm Hg)	70	61-80	74	66-83
Heart rate (beats/min)	80	72-104	84	76-108

group four women smoked 10 to 20 cigarettes per day, in comparison with three women in the placebo group. The dose of aspirin at 28 weeks' gestation was 0.9 ± 0.2 mg/day/kg body weight (mean ± SD).

One woman in the aspirin group withdrew from the study immediately after randomization. The angiotensin II sensitivity test was not repeated in three women in the placebo group, because they had become hypertensive (diastolic blood pressures of 95 to 110 mm Hg) before 34 weeks' gestation; in the aspirin group all women were normotensive at 34 weeks. In the placebo group the mean (±SD) value of thrombin-induced malondialdehyde production per 10^9 platelets at 34 weeks' gestation was 4.5 (±1.0) nmol, in comparison with 0.48 (±0.2) nmol in the aspirin group ($p < 0.001$); the highest value determined in the aspirin group was 1.0 and the lowest value in the placebo group was 2.8 nmol/10^9 platelets. The mean (±SD) number of days during which medication was taken in the aspirin group (40 ± 3) was not different from that in the placebo group (41 ± 4).

The median effective pressor dose at 28 weeks' gestation was 7.5 ng/kg/min in both groups (Table II). The effective pressor dose at 34 weeks was significantly higher than at 28 weeks in the aspirin group ($p < 0.01$) but not in the placebo group (Fig. 1). Seven women in the placebo group but none in the aspirin group showed a decrease in the effective pressor dose between 28 and 34 weeks' gestation ($p < 0.01$). At 34 weeks' pregnancy 14 women in the aspirin group, as compared with five in the placebo group, showed an effective pressor dose of >10 ng/kg/min ($p = 0.02$); all these women had effective pressor doses of 11 or 12 ng/kg/min, except one woman in the aspirin group with an effective pressor dose of >12 ng/kg/min in whom the actual value was not determined. When the effective pressor dose was reached during angiotensin infusion, maternal heart rate showed a significant fall of 8 to 10 beats/min before and after treatment ($p < 0.01$); the fall in maternal heart rate was not different between groups (Table II).

Since some of the women had been taking a low dose of aspirin after 34 weeks' gestation and others had not, the outcome of pregnancy was not analyzed. All infants were live-born, and serious neonatal problems were not encountered.

Table II. Angiotensin II sensitivity before the start of treatment with aspirin or placebo at 28 weeks and at the end of treatment at 34 weeks' gestation

	Aspirin (n = 17)	*Placebo (n = 15)*

At 34 wk	74 (60-84)*	76 (48-98)†
No. of women with effective pressor dose > 10 ng/kg/min		
At 28 wk	0	0
At 34 wk	14	5

*Effective pressor dose reached in 13 women.
†Effective pressor dose reached in 15 women.

Comment

The values of thrombin-induced production of malondialdehyde by platelets in both groups of women indicate that they had complied with the prescribed regimen. The observation that three of 18 women in the placebo group had already become hypertensive before 34 weeks' gestation is in accordance with the results of previous studies on the predictive value of the angiotensin II sensitivity test, a level of 10 ng/kg/min used as the threshold dividing normal and abnormal angiotensin sensitivity.[12] The results of our trial indicate that daily ingestion of 60 mg of aspirin from 28 to 34 weeks' gestation significantly reduces the vascular responsiveness to angiotensin II in angiotensin-sensitive primigravid women. In 82% (95% confidence interval, 57% to 95%) of 17 treated women

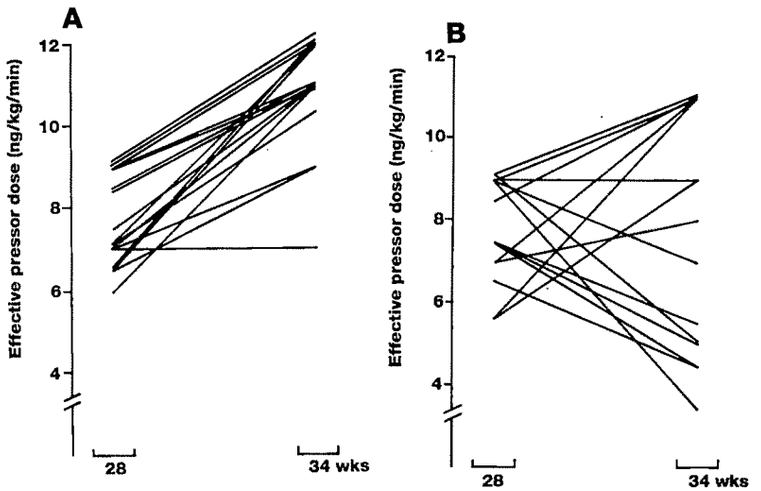

Fig. 1. Minimum amount of angiotensin II (nanograms per kilogram per minute) infused intravenously causing a rise in diastolic blood pressure of 20 mm Hg (effective pressor dose). **A,** In 17 primigravid women at 28 weeks' gestation before and at 34 weeks after 6 weeks of daily oral ingestion of 60 mg of aspirin. **B,** In 15 primigravid women at 28 weeks' gestation before and at 34 weeks after 6 weeks of daily oral ingestion of matched placebo.

but in only 33% (95% confidence interval, 12% to 62%) of 15 women in the placebo group, the effective pressor dose returned to values >10 ng/kg/min. The difference may in fact be more pronounced because of the exclusion of the three women in the placebo group who had become hypertensive at 34 weeks' gestation and, for that reason, most likely had enhanced angiotensin II sensitivity at that time. The fall in heart rate during the effective pressure dose of angiotensin II has been observed by other investigators and may be explained by baroreflex function.[14] Since the fall in heart rate that occurred when the effective pressor dose was reached was equal in both groups, baroreceptor response was apparently not influenced by low doses of aspirin.

Our results are consistent with those of a recent trial in which 22 angiotensin-sensitive women were treated at about 33 weeks' gestation with 81 mg of aspirin during a 1 week period.[14] In that study the mean effective pressor dose increased from 5.9 to 10.2 ng/kg/min, and values of ≥10 ng/kg/min were obtained in 53% of 17 women studied before and after 1 week of low doses of aspirin. However, the study was not placebo controlled or blinded. In an earlier, also uncontrolled study conducted in 13 primigravid women with a physiologic angiotensin refractoriness, the effective pressor dose 2 hours after a single oral dose of 80 mg of aspirin was found to be twice that before treatment.[15] In contrast, oral ingestion of 650 mg of aspirin twice with an interval of 6 hours between doses has been demonstrated to lead to a marked increase in angiotensin sensitivity in pregnant women.[16] The contrasting effect of low and high doses of aspirin may be explained by the finding in various controlled studies in pregnancy[10, 11] and in nonpregnant[17] subjects that long-term administration of aspirin in a daily dose between about 40 and 80 mg markedly reduces the production of platelet thromboxane A_2 while sparing the synthesis of vascular prostacyclin; cumulative higher doses result in progressive inhibition of vascular prostacyclin biosynthesis.[17] The demonstrated selective inhibition of platelet thromboxane A_2 by low doses of aspirin is thought to be due to cumulative presystemic inhibition of cyclooxygenase in platelets passing through gut capillaries with a relatively high concentration of aspirin after oral ingestion, whereas the concentration in the systemic circulation remains too low to affect the enzyme in vascular endothelium.[18] In addition, there are approximately 1000 times as many vascular endothelial cells capable of forming prostacyclin as platelets producing thromboxane A_2.[19] Although we did not measure serum concentrations or urinary excretion of eicosanoid metabolites, the inhibition of the thrombin-induced formation of malondialdehyde by platelets to approximately 10% of the placebo values indicates suppression of thromboxane A_2 dominance and is consistent with the results of other studies in which these metabolites were determined.[10, 11, 14, 20]

Several randomized, placebo-controlled and blinded studies have now confirmed the original report[21] that low doses of aspirin reduce the incidence of pregnancy-induced hypertensive disorders in women with various risk factors,[10, 11, 22] including increased angiotensin sensitivity,[9] most likely because of suppression of platelet thromboxane synthesis and restoration of relative prostacyclin dominance.[10, 11] The finding that a low dose of aspirin improves vascular refractoriness in angiotensin-

sensitive primigravid women supports the hypothesis that enhanced vasopressor sensitivity to angiotensin II is a pathophysiologic mechanism in the development of pregnancy-induced hypertensive disorders associated with an imbalance in prostacyclin–thromboxane A_2 synthesis. The mechanism through which such an imbalance affects vascular reactivity is not fully understood. The vasoconstrictor action of angiotensin II may be enhanced because of an insufficient, direct antagonizing effect of vasodilator prostacyclin. However, the results of a recent study on platelet angiotensin II binding sites[23] suggest that a lack of down regulation of angiotensin II receptors also could be involved.

Morphologic changes in the human amnion epithelium that accompany labor as seen with scanning and transmission electron microscopy

Jiri Sonek, MD, Steven G. Gabbe, MD, Jay D. Iams, MD, and Douglas A. Kniss, PhD
Columbus, Ohio

Scanning and transmission electron microscopy were used to assess the influence of normal, active labor on the ultrastructure of the human amnion epithelial membrane. Amnion membranes (reflected and placental portions) were obtained from patients either in active labor who were delivered vaginally or by cesarean section after 6 to 12 hours of labor or from patients who underwent elective cesarean section before clinical signs of overt labor. Scanning electron microscopy revealed that reflected amnion membranes that were obtained from patients who were not in labor consisted of a uniform single layer of epithelial cells with numerous microvilli on the apical surface and closely associated cellular borders. In contrast, amnion membranes that were obtained from patients who were in labor consisted of a single layer of epithelial cells, which was interupted by wide intercellular gaps and extracellular extrusions. Transmission electron microscopy showed that intercellular junctions tended to be less complex in patients who were in labor versus patients who were not in labor. Although lipid droplets were prevalent in both patient groups, specimens that were obtained from patients who were in labor had more lipid droplets per cell than specimens from patients who were not in labor. These results support the theory that the complex biochemical events that culminate in parturition are accompanied and/or preceded by demonstrable morphologic changes in the amnion membrane. (Am J Obstet Gynecol 1991;164:1174-80.)

Key words: Parturition, ultrastructure, amnion epithelium, electron microscopy

The microanatomy of the human fetal membranes has been studied previously by a number of investigators.[1-5] It has been noted that the amnion epithelial cells are heterogeneous with respect to light microscopic appearance; there are both "light and dark" staining cells with hematoxylin and eosin.[6-8] Ultrastructural studies have demonstrated that amniotic cells exhibit varying degrees of intracellular vacuolation and lipid droplet accumulation.[3] The fetal membrane specimens that were examined in these previous studies were controlled for a number of clinical parameters that could affect histologic appearance including chorioamnionitis, meconium, and defects that are attributable to birth trauma. One factor, however, which was not taken into account was the influence that active labor had on the structure of the amnion epithelium.

Thus the present investigation was undertaken to examine whether the process of parturition is accompanied by demonstrable morphologic changes in the human amnion epithelium. Reflected amnion and amnion that overlies the placenta from patients at term were examined with scanning and transmission electron microscopy. Amnion membranes were also obtained from patients who were delivered by elective cesarean section without overt signs of active labor. Amnion membranes from patients who were in spontaneous labor were obtained at the time of vaginal delivery in which active labor was 6 to 12 hours in duration.

Patients and methods

Tissue. Placentas were procured from patients after term delivery (38 to 41 weeks' gestation). Placentas and fetal membranes are excluded under category 5 of the National Institutes of Health guidelines for use of tissues from human subjects. Thus written consent for their collection was not obtained. Confidentiality of patients' identities was protected at all times. Patients with meconium staining, oligohydramnios, hydramnios, or

suspected chorioamnionitis were excluded from the study. There were no identifiable maternal or fetal risk factors and the patients had not received any medications, including tocolytic agents. Three placentas were obtained from patients with no history of contractions who were delivered by elective cesarean section. One of these patients was primigravid and underwent elective cesarean section for fetal malpresentation, whereas the other two patients were multigravid and had elective repeat cesarean sections. Three placentas were obtained from patients who presented in active labor. The time interval from presentation until delivery ranged from 6 to 12 hours. One primigravid patient received oxytocic augmentation of labor and subsequently underwent a cesarean section for cephalopelvic disproportion after approximately 12 hours of labor. The remaining two multigravid women had normal spontaneous vaginal deliveries after 6 to 12 hours of labor.

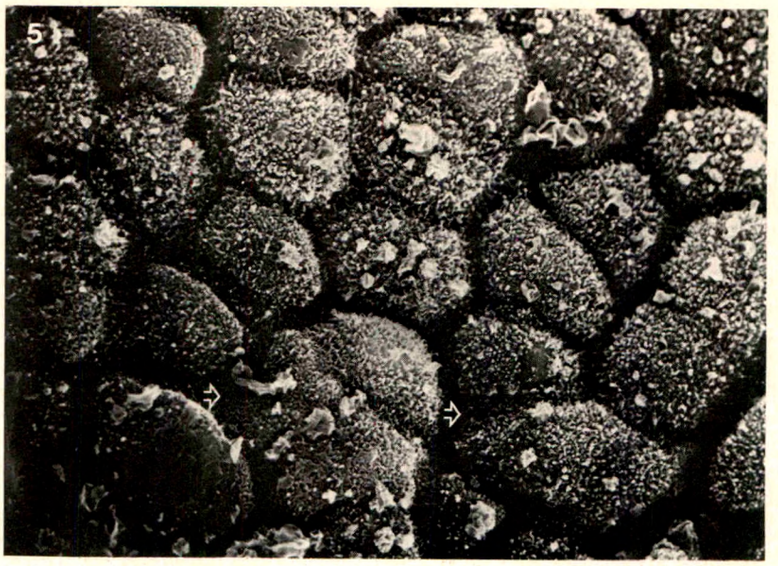

Fig. 5. Scanning electron micrograph of placental portion of amnion epithelium from a patient who was in labor. *Open arrowheads* show wide intercellular spaces. (Original magnification ×3120.)

The placentas and membranes were carefully inspected to rule out any grossly demonstrable abnormalities. All tissues were processed less than 30 minutes after delivery.

Tissue processing. The amnion reflectum was stripped from the underlying chorion, and the placental amnion was stripped from the placental surface. Great care was taken to limit handling of the tissues to minimize trauma-related artifacts. The amnion was then rinsed with sterile phosphate-buffered saline, cut into small pieces (approximately 5 mm^2) and placed in a solution that contained 2.5% glutaraldehyde in 0.1 mol/L phosphate buffer with 5% sucrose for 60 to 75 minutes. The specimens were again rinsed and serially dehydrated in acetone of increasing concentrations from 50% to 100%. Each sample was then divided into two parts, one for preparation for transmission electron microscopy and the other for scanning electron microscopy. In preparation for transmission electron microscopy, the tissue was embedded overnight in Spurr's resin at 60° C. Thick sections (0.5 μm) were cut with glass knives and stained with 1% toluidine blue in borate buffer for orientation. Thin sections (80 to 100 nm) were cut with glass knives and transferred to copper mesh grids. Sections were stained with lead citrate and uranyl acetate and examined with a Philips 300 transmission electron microscope (Philips Electronic Instruments Inc., Mahwah, N.J.) at 60 kV.

In preparation for scanning electron microscopy, the specimens were freeze-dried in a critical point dryer (Pelco 1200, Redding, Calif.) and were then sputtered-coated with gold and platinum. The specimens were examined with a Philips CM-12 scanning-transmission electron microscope in the scanning mode at 40 kV. Amnion reflectum and placental amnion from all six patients were successfully examined by transmission electron microscopy and scanning electron microscopy. At least two preparations from each site were examined with both methods.

Results

Scanning electron microscopy findings

Amnion reflectum. In the tissues that were obtained from patients who were not in labor, the amnion epithelium consisted of a sheet of closely apposed cells with numerous microvilli that projected from the apical surface (Fig. 1). The apical (adluminal) surface of the amnion in patients who were not in labor was more uniform and devoid of cellular extrusions. In specimens that were obtained from patients who were in labor, the intercellular junctions appeared to be widely separated (Figs. 2 and 3; large arrows) and numerous extracellular extrusions (Figs. 2 and 3, small arrows) were noted. The appearance of microvilli was largely unchanged.

Placental amnion. The amnion epithelium from patients who were not in labor consisted of a sheet of cells with poorly defined cellular borders (Fig. 4). The cells appeared to have a raised centrally located area with extracellular material that overlaid it. Infrequently, ostia to intercellular channels were observed (Fig. 4; open arrowheads). The structures of the specimens from patients who were in labor were very different from those in patients who were not in labor. The definition of the cellular borders was more pronounced, and in many places, there were wide intercellular gaps (Figs. 5 and

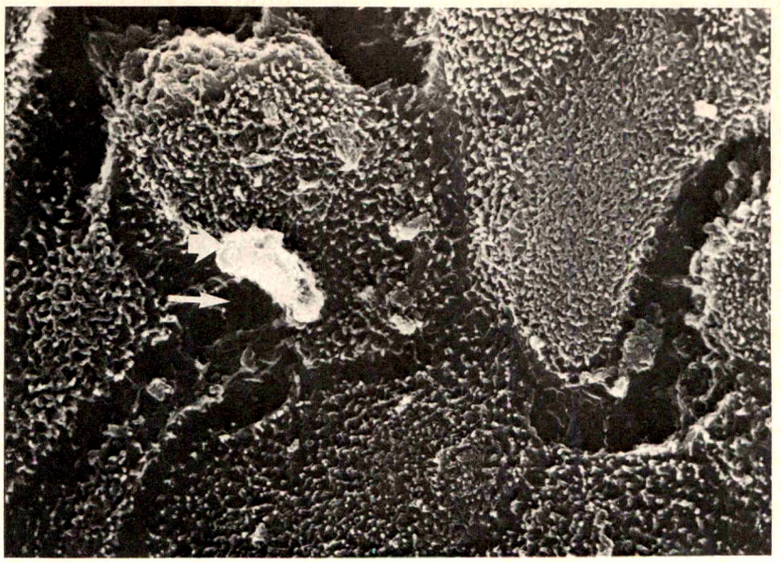

Fig. 6. Scanning electron micrograph of placental portion of amnion epithelium from a patient who was in labor. *Arrowhead* shows extracellular material on surface of epithelial cell. *Arrow* shows opening to intercellular channel. (Original magnification ×7360.)

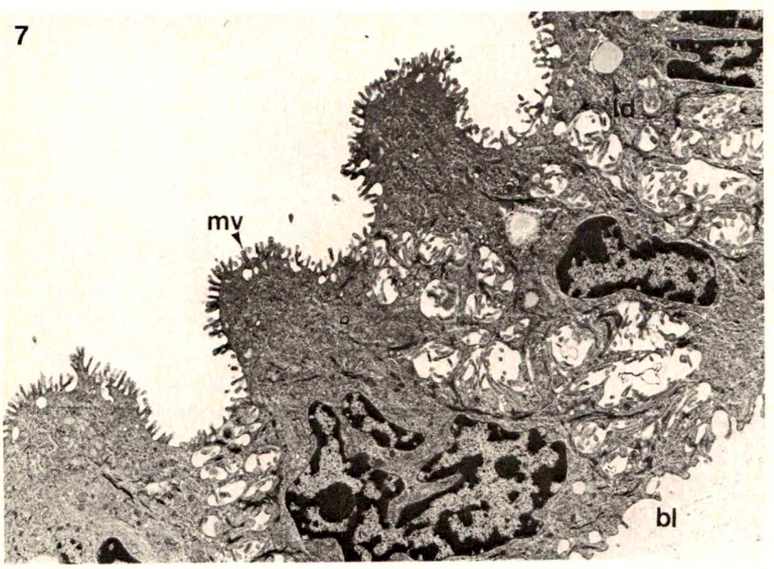

Fig. 7. Transmission electron micrograph of reflected portion of amnion epithelium from a patient who was not in labor. *mv*, Microvilli; *ld*, lipid droplets; *bl*, basal lamina. (Original magnification ×45,900.)

6; open arrowheads). Ostia to the intercellular channels were more numerous in the placental amnion (Figs. 5 and 6; arrows). The extracellular material that overlaid the surface of the cells was largely replaced by clumps of amorphous material of smaller size (Fig. 6; large arrowheads).

Transmission electron microscopy findings

Amnion reflectum. The reflected amnion epithelium in both the patients who were in labor (Fig. 7) and those who were not in labor (Fig. 8) consisted of cuboidal to low columnar cells with centrally located nuclei. The amnion epithelial cells in specimens from patients who

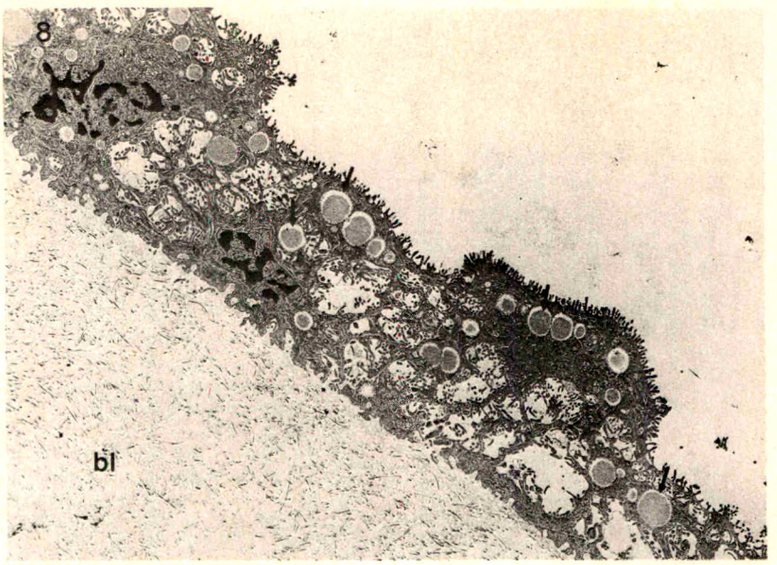

Fig. 8. Transmission electron micrograph of reflected portion of amnion epithelium from a patient in labor. *Arrows* indicate lipid droplets. *bl*, Basal lamina. (Original magnification ×45,900.)

were not in labor were columnar with numerous microvilli that projected from the apical surface (Fig. 7), whereas specimens that were obtained from patients who were in labor had cuboidal epithelial cells. The intercellular junctions in specimens from patients who were in labor tended to be looser and to assume more of a labyrinthine pattern than in those from patients who were not in labor. Similarly, the cellular processes at the base of the cells where they attached to the underlying basal lamina were longer and more complex in the amniotic specimens from patients who were not in labor.

Lipid droplets appeared to be more numerous in the amniotic membranes from patients who were in labor, although they were both present in both groups of specimens (Fig. 8). Further morphometric analysis will be required to ascertain whether these differences are statistically significant. There did not appear to be a consistent difference in the appearance of the nucleus and other cytoplasmic organelles in specimens from patients who were in labor versus specimens from patients who were not in labor.

Comment

The present investigation was undertaken to determine whether the process of normal, active labor influences the ultrastructural features of the human amnion epithelium. Although others have studied the structure of the amnion at term, to our knowledge, this is the first study to be reported in the literature in which the influence of labor was assessed. The human fetal membranes (amnion and chorion laeve) are believed to play a vital role in the maintenance of intrauterine integrity during gestation. The amnion is also known to liberate arachidonic acid and synthesize prostaglandin E_2, which is involved in the initiation of parturition.[9, 10] Our present findings further indicate that these biochemical events are accompanied by or preceded by demonstrable ultrastructural changes in both placental and reflected portions of the amnion membrane.

As a control for the influence of labor on amnion ultrastructure, specimens were obtained from several patients who were delivered by elective cesarean section without overt signs of labor. In these preparations, with the use scanning electron microscopy, the amnion was seen as an intact cellular membrane. In contrast, in patients who presented with overt clinical signs of active labor, the cells of the amnion membrane appeared to be less tightly associated, and large intercellular extrusions between the cells were noted. The nature of these extrusions is not known at the present time. Another intriguing observation was the presence of large amounts of lipid droplets in specimens that were obtained from patients in active labor as compared with patients who were not in labor. Although it must be noted that lipid droplet accumulation was seen in both patients who were in labor and patients who were not in labor, demonstrably more lipid was found in specimens from patients who were not in labor.

In summary, our findings of clearly demonstrable changes in the ultrastructure of the human amnion membrane as a function of active labor lend further

support for an important role of this tissue in the parturitional process. Whether these morphologic changes are the result of the complex biochemical events that take place during labor or are simply ancillary events must await future studies.

We thank Kathleen Wolken and Karen Zaruba for their excellent technical assistance with the electron microscopy. The assistance of Michael Waxman in preparing the electron micrographs and the manuscript is gratefully acknowledged. This work was completed while Dr. Sonek was a fellow in Maternal-Fetal Medicine at The Ohio State University.

Bound volumes available to subscribers

Bound volumes of the American Journal of Obstetrics and Gynecology are available to subscribers (only) for the 1991 issues from the Publisher, at a cost of $61.00 for domestic, $88.27 for Canada, and $84.00 for international for Vol. 164 (January-June) and Vol. 165 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the Journal name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular Journal subscription.

Fibrocystic disease of the breast in premenopausal women: Histohormonal correlation and response to luteinizing hormone releasing hormone analog treatment

Joseph Monsonego, MD,[a] Marie-Dominique Destable, MD,[b] Georges De Saint Florent, MD,[b] Jacques Amouroux, MD,[c] Jean-Claude Kouyoumdjian, MD,[d] France Haour, PhD,[e] Jean-Luc Breau, MD,[a] Lucien Israel, MD,[a] Ana-Maria Comaru-Schally, MD,[f] and Andrew V. Schally, PhD, MD[f]

Bobigny, Creteil, and Paris, France, and New Orleans, Louisiana

Sixty-six patients with fibrocystic mastopathy were enrolled in the trial after being selected according to clinical, radioultrasonographic, and histologic criteria. No characteristic hormonal profile was noted in most patients (52%). Estrogen receptors or progesterone receptors, or both, were found in 57% of patients. Hormone receptor levels were correlated with atypical proliferative mastopathy (87.5%). Mastopathy was associated with a uterine fibroma or a fibromatous uterus in 73% of cases. All patients received intramuscular injections of a sustained delivery system (microcapsules) of luteinizing hormone releasing hormone agonist [D-Trp^6]-LHRH, Ipsen-Biotech, Paris) for 3 to 6 months. In case of partial response at 3 months, an antiestrogen (tamoxifen, 40 mg/day, for estrogen receptor–predominant lesions) or a progestin (cyproterone acetate, 50 mg/day, for progesterone receptor–predominant lesions) was added to the luteinizing hormone releasing hormone agonist. A complete response was observed in more than half of the patients (n = 35, 53%) treated by [D-Trp^6]-LHRH alone (n = 29) or associated with tamoxifen (n = 4) or cyproterone acetate (n = 2). A significant partial response was observed in 30 other patients (45%). Additionally, half of them received inhibitory drugs. The best responses were seen with cyst reformation (complete response, 100%) and fibrous block. Clinical responses to treatment with [D-Trp^6]-LHRH alone were independent of hormone receptor status, but synergistic effects occurred with concomitant use of the corresponding inhibitory drugs. We conclude that chronic mastopathy, particularly when associated with uterine fibroma, can be successfully treated by luteinizing hormone releasing hormone analogs in premenopausal women. (Am J Obstet Gynecol 1991;164:1181-9.)

Key words: Proliferative mastopathy, estradiol receptors, luteinizing hormone releasing hormone analog

The risk of breast cancer is increased in patients with fibrocystic mastopathy when it is associated with epithelial proliferation or family history of cancer.[1] Fibrocystic disease has been interpreted as the result of gonadal or hypothalamic-hypophysial hormonal disorders,[2] but hormonal anomalies[3] or hormonal receptors[4] are not consistently found. Results of various hormonal treatments, including progestins, are incomplete and controversial.[5, 6]

In view of our experience regarding the frequent association of high-risk benign mastopathy with uterine fibromas and the possible effects of luteinizing hormone releasing hormone (LHRH) analogs on both these diseases[7] and in consideration of the reported direct effect of these analogs on breast carcinoma cells,[8, 9] we decided to evaluate the efficacy of [D-Trp^6]-LHRH in chronic fibrocystic mastopathy in premenopausal women with a high risk of breast carcinoma.

Material and methods

Patients. Sixty-six female patients with a mean age of 43 years (range, 31 to 50) participated in this preliminary study, after selection on the basis of criteria of high-risk benign mastopathy.[1] All patients had a regular menstrual cycle of 28 to 30 days and were not using any other drugs.

Fifty patients were premenopausal (mean age, 43.4 years), eight were approaching menopause (mean age, 50.2 years), and eight had undergone conservative total

Table I. Histologic characteristics of mastopathy (according to the Dupont-Page classification)

	No.	%
Nonproliferative disease	10	15
Proliferative disease	56	85
Without atypical hyperplasia	46	70
Typical lobular hyperplasia, including sclerotic adenosis	24 4	36.3
Typical ductal hyperplasia	14	21.2
Pure stromal hyperplasia	5	7.5
Lobular and ductal hyperplasia	3	4.5
With atypical hyperplasia	10	15
Atypical lobular hyperplasia	1	1.5
Atypical ductal hyperplasia (type II-III)	7	10.6
Epitheliosis-papillomatosis (type IV)	2	3

hysterectomy (mean age, 44.7 years). Painful symptoms (58.9%), congestion (60.9%), or hyperesthesia of the nipple (10.15%) was noted in 62 patients (94%). Symptoms was marked in 34 patients (51%), moderate in 22 cases (34%), and mild in 8 (12%). Mastodynia was cyclic in more than three quarters of the cases and continuous in the other 12 cases (18%).

Forty-eight patients (72%) had a family history of cancer, including breast cancer (n = 30) or cancer of the colon (n = 16). A family history of both breast cancer and cancer of the colon was noted in eight cases.

Eight patients (12%) had a history of breast cancer. Twenty-four patients (37%) had undergone breast biopsy and 10 (15%) were obese.

More than half the patients (34/58) were resistant to progestins, and aggravation of mastopathy was noted in 16 patients during treatment. Therapy with tamoxifen alone (30 mg/day) was ineffective in 10 of 30 cases.

Mastopathy. Clinical and radiologic (ultrasonography and mammography) characteristics of mastopathy without regard to histologic findings were noted: macrocysts only (10 cases, 15%); nodules only (16 cases, 25%); fibrous block only (4 cases, 6%); heterogeneous (macrofibronodular) consisting of nodules, cysts, and blocks of various sizes (30 cases, 45%); microcysts only (2 cases, 3%); and clinically normal breasts (4 cases, 6%). This last class of patients was included because of the presence of mastodynia, multipore nipple discharge, radiologically dense breasts, and proliferative mastopathy. Histologic characteristics of mastopathy (according to the Dupont-Page classification[1]) are shown in Table I. Proliferative mastopathy was noted in 56 of 66 cases (85%), and cellular atypia was seen in 10 of the cases (15%), including atypical lobular hyperplasia (n = 1), atypical ductal hyperplasia (n = 7), and epitheliosis (n = 2).

Clinical correlation of histologic findings. Benign mastopathy was heterogeneous. Macrocystic mastopathy (n = 10) was associated with proliferative lesions in four cases (40%), including two with cellular atypia, and nodular mastopathy (n = 16) in 14 cases (80%), including two with cellular atypia. Mastopathy with fibrous block (n = 4) and microcysts (n = 2) was always associated with proliferative lesions, but cellular atypia were absent. Heterogeneous mastopathy (n = 30) was proliferative in 28 patients (94%), including two with cellular atypia. No significant histologic and clinical correlation could be established in this risk group. Proliferative and nonproliferative mastopathies were frequently associated.

Gynecologic examination. Fifty-eight patients (88%) had cyclic menses. The other eight patients had undergone conservative hysterectomy because of fibroma. Fibroma was or had been present in 48 patients (73%), and the uterus was fibromatous in 22 cases (33%). Interstitial or subserous myoma was seen in 16 patients (24%), and one case of submucous myoma was confirmed hysterographically. Polycystic ovaries were seen in six patients (9%) and ovarian endometriosis confirmed by laparoscopy in two patients. Hormonal analysis of plasma prolactin, estradiol, and progesterone was carried out on the twenty-first day of the cycle by double-antibody radioimmunoassay. Three populations were identified: (1) 20 patients (30%) with absolute or relative hyperestrogenism (progesterone/estradiol ratio in nanograms per milliliter, <0.8); (2) 12 patients (18%) with overt hyperprolactinemia (prolactin level, >20 ng/ml) and a normal sella turcica, as assessed by computerized tomographic scan; (3) 34 patients (52%) without hormonal disorders.

Steroid receptor analysis. Analysis of breast biopsy specimens removed surgically on days 20 to 23 of the cycle was used to confirm the presence or absence of hormone receptors (estrogen, progesterone).

Estrogen and progesterone receptors were measured by dextran-charcoal assay. Briefly, fat and connective tissue were removed from tumor specimens, which were then snap frozen and stored at −70° C until assay. Frozen tissue was pulverized, and the powder was thawed and homogenized in assay buffer (0.02 mol/L Tris hydrochloride, 0.04 mol/L sodium molybdate, 10% glycerol, 0.4 mol/L potassium chloride, 0.0015 mol/L ethylenediaminetetraacetate, 0.0025 mol/L dithiothreitol, pH 7.4) with a Polytron (Bioblock Scientific, 67403 Illkirch, France) homogenizer. After centrifugation at 100,000 g for 60 minutes, aliquots of the supernatant were incubated with 7 nmol/L [^{3}H]17β-estradiol or 20 nmol/L ^{3}H-ORG 2058 (Amersham) in the presence of either a 100-fold excess of unlabeled diethylstilbestrol or assay buffer. After a 16-hour incubation at 4° C, bound and free labeled hormone was separated with dextran charcoal. Cytosol binding ca-

pacity, calculated from the difference between bound and free radioactivity, correlated significantly with the Scatchard analysis ($r = 0.97$, $n = 45$ for estrogen receptors; $r = 0.96$, $n = 16$ for progesterone receptors) of the results of assays performed in parallel with various concentrations of labeled hormone. All results were expressed per milligram of cytosol protein, as determined by the method of Lowry et al. Levels of estrogen and progesterone receptors >10 fmol/mg cytosol protein were defined as significant. Receptor assay was not possible in six patients. Estrogen-receptor protein was present (estrogen receptor positive; mean, 84 fmol/mg protein) in 26 cases (44%) and progesterone-receptor protein was present (progesterone receptor positive; mean, 112 fmol/mg protein) in 24 cases (40%). Eighteen patients (30%) were both estrogen and progesterone receptor positive, and 28 patients (43%) were both estrogen and progesterone receptor negative. This is probably due to tissue heterogeneity of the lesions and is in agreement with previous findings.[4, 10] In contrast to the case of breast adenoma,[11] no clear correlation was noted here between receptor content and estradiol and progesterone levels during the menstrual cycle. This likely reflects probably unregulated genomic control of receptor levels at the lesion boundary, as seen in breast cancer.[12] There was no significant correlation between the clinical type of mastopathy and the hormone receptor content. There was, however, a clear correlation between epithelial proliferation with cellular atypia and hormone receptor content. Of 10 cases of atypical proliferative mastopathy, eight of which were assayed for hormone receptors, seven (87.5%) showed elevated levels and six were classified as estrogen receptor positive. Six of 10 cases (60%) of non-proliferative mastopathy were classified as hormone receptor negative. Four of five (80%) cases of pure stromal hyperplasia were classified as hormone receptor negative. These results corroborate literature reports that hormone receptor levels, estrogen receptor levels in particular, are correlated with the degree of epithelial hyperplasia.[4, 10, 11]

LHRH receptors analysis. LHRH receptors on biopsy specimens can be visualized and measured by quantitative autoradiography.[13] Frozen slices are exposed to a radioactive tracer ([D-Ala^6]-LHRH ethylamide labeled with iodine 125; specific activity, 2000 Ci/mmol). After incubation and washing, the slices are placed over radiosensitive films (Amersham ^{3}H Hyperfilm, Amersham, 91944 Les Ulis, France). After exposure, the pictures are quantified by picture analysis (Biocom, Rag 2000). This technique of direct visualization does not show specific (high-affinity) receptors in the biopsy specimens of mastopathy; the appearance of nonspecific receptors is significant in the vascular coating (low affinity and high capacity) in particular, and the marker does not correlate with the presence of specific receptor sites.

Treatment. Informed consent was obtained from all patients before treatment with the long-acting LHRH analog [D-Trp^6]-LHRH (Ipsen-Biotech, Paris) administered every 4 weeks by intramuscular injection of 3.75 mg in the form of sustained-release microcapsules releasing 100 μg analog per day for 28 days. The first injection was given in the first 5 days of the menstrual cycle. After 3 months, treatment was modified according to the response: For a complete response, treatment was discontinued; for a partial response, in all cases treatment with [D-Trp^6]-LHRH was continued for three more months in combination with tamoxifen 40 mg/day for patients with estrogen receptor–predominant lesions or cyproterone acetate 150 mg/day in cases of progesterone receptor–predominant lesions.

These therapies were chosen for their estrogen-antagonist property in benign mastopathy.[5-11] Tamoxifen counteracts the proliferative effect of estrogens by competing with them at the estradiol receptor level. Cyproterone acetate is a progestin, and therefore one of its effects is to yield a decrease in estradiol receptor concentration. This antiandrogen is well tolerated. It has no negative metabolic effect such as norsteroid progestins have.

Moreover, the hypothalamic-pituitary-ovarian axis blockade by [D-Trp^6]-LHRH suppresses the consequences of the clomiphene-like effect of tamoxifen and the metrorrhagia induced by cyproterone acetate before the menopause.

Clinical and radiologic evaluation of mastopathy. The size and number of cysts, nodules, or blocks evaluated during examination at the third and sixth months were compared with the results of the first examination. The response was considered complete when these structures were no longer present at 3 or 6 months. The response was considered partial when the mean diameter of mastopathy structures had decreased after treatment. These decreases ranged from 20% to 80%. Any effects of the concomitant use of tamoxifen and cyproterone acetate were evaluated and scored as synergistic, nil, or antagonistic. A second clinical and gynecologic evaluation was performed after the six treatment cycles. This was supplemented by comparative mammography, mammary and pelvic ultrasonography, and hormonal analysis that was identical to that performed at the start of the trial.

Results

Mastopathy

Mastodynia. Pain was absent in all cases ($n = 62$, 100%) after 2 months of treatment. Exacerbation of mastodynia was seen in 18 cases (28%) between day 0

and day 15. This corresponded to the first stage of hormonal stimulation. These symptoms subsided around day 20 in all cases.

Clinical and radiologic (ultrasonography-mammography) responses according to type of mastopathy. Stabilization and regression (complete response) were seen after 3 months in all cases of macrocystic mastopathy (n = 10) previously treated by cyst aspiration. Pure fibronodular mastopathy (n = 16) had subsided completely at 6 months in 25% of cases (4/16). Nodules decreased in number and volume at 6 months in 50% of cases (8/16). A favorable response was induced in the remaining patients (25%) by concomitant use of tamoxifen (2 cases) or cyproterone acetate (2 cases) with [D-Trp^6]-LHRH from the third month to the sixth month (when the receptor status was estrogen receptor positive or progesterone receptor positive, respectively). In mastopathy involving fibrous block (n = 4), the volume of affected tissue had decreased by less than half in two cases. Concomitant use of cyproterone acetate during the last 3 months of treatment resulted in a 60% regression in fibrous block in two other patients (progesterone receptor positive). Heterogeneous (n = 30) or macrofibronodular mastopathy had subsided completely at 6 months in 16 patients, six of whom had received either tamoxifen (n = 4, estrogen receptor positive) or cyproterone acetate (n = 2, progesterone receptor positive) as a companion drug during the last 3 months of treatment. The volume of affected tissue decreased approximately twofold in one patient after 3 months. Overall, the most frequent mastopathy disappeared in 54% of cases after 6 months and subsided more than twofold in the other 46%. Microcystic mastopathy (2 cases) regressed completely at 3 months (complete response, 100%).

After 6 months of treatment with [D-Trp^6]-LHRH alone, multiple surgical biopsy specimens were done to evaluate atypical proliferative mastopathy in four patients with clinically normal breasts. No epithelial hyperplasia was noted in any of the biopsy specimens taken from three of the four patients. Cellular atypia was still present in one patient.

Response in terms of symptoms is recorded in Table II. Nodules (n = 42) regressed completely at 6 months in six patients (15%) and had decreased in size and number in 17 patients receiving [D-Trp^6]-LHRH alone, in 12 women treated with the combination of [D-Trp^6]-LHRH and tamoxifen (estrogen receptor), and in seven patients receiving concomitant cyproterone acetate (progesterone receptor positive). Regression (complete response) of fibrous block (n = 34) was noted in 12 patients (35%) at 6 months. The volume of fibrous block was reduced to one half in the remaining 19 patients (56%) receiving [D-Trp^6]-LHRH alone (n = 20) or in combination with cyproterone acetate (progesterone receptor positive, n = 2). When cysts (n = 12) were aspirated, recurrence was not seen (complete response, 100%) after 3 months of treatment. Multipore nipple discharge without cytologic anomalies (n = 18) resolved after 6 months of treatment in 12 patients (67%) and decreased in the other 6 (33%). Hypermastia diminished by 30% in 10 of 14 patients (70%).

In 45 patients receiving [D-Trp^6]-LHRH alone, complete responses were noted in 29 (65%) at 3 (n = 12) or 6 months (n = 17). Partial responses were recorded in 15 patients (33%) at 3 (n = 1) and 6 months (n = 14). One patient with proliferative mastopathy without clinical failure had no response after histologic control. Responses were not complete after 3 months of treatment with [D-Trp^6]-LHRH in 21 patients, 19 of whom were classified as hormone receptor positive. At 6 months, after concomitant use of cyproterone acetate (n = 9) or tamoxifen (n = 12), complete regression was noted in 6 of these patients (28%), 80% regression in 10 (48%), and 60% regression in five (24%). Resolution of all types of mastopathy was noted in 35 cases (53%),

12 at 3 months and 23 at 6 months. More than twofold regression in mastopathy was noted in other cases (n = 30), at 3 (n = 1) or 6 (n = 29) months (Table III). Mammography at 6 months indicated a clear decrease in glandular density in the majority of cases (Fig. 1).

Clinical, ultrasonographic, and mammographic responses according to hormonal receptor status. The responses of nodules, cysts, and fibrous block to treatment were independent of hormone receptor status, but synergistic response was noted with concomitant use of antisteroidal agents (tamoxifen and cyproterone acetate). Complete remission was most frequent (71.5%) in the estrogen and progesterone receptor–negative group, which was characterized by the absence of cellular atypia and which was treated with [D-Trp^6]-LHRH alone. Hormone-dependent lesions (estrogen and

‡Hormone receptor positive: estrogen receptor positive and progesterone receptor negative, estrogen receptor negative and progesterone receptor positive, estrogen and progesterone receptor positive.

progesterone receptor positive, estrogen receptor negative and progesterone receptor positive, estrogen receptor positive and progesterone receptor negative) responded to treatment with [D-Trp⁶]-LHRH alone (9/32) and to combination therapy with [D-Trp⁶]-LHRH with tamoxifen or with cyproterone acetate during the last 3 months after a partial response (15/32). In the case of tamoxifen, synergism was particularly correlated with estrogen receptor–positive cases, which in this study were most often associated with cellular atypia (Tables IV and V).

Associated gynecologic anomalies. Mastopathy was associated with a fibromatous uterus or uterine myoma in 48 patients. In 26 cases of fibromatous uterus a complete remission was noted at 3 and 6 months with a return to normal size in eight and six cases, respectively; i.e., complete response was achieved in 54% of cases. Uterine volume decreased by >50% (partial response) in eight other patients. No response was noted in four obese patients. No response to treatment was noted in two cases of submucous myoma. Partial responses (>50%) were seen in 18 of 20 patients with subserous and interstitial myoma. Overall, for all types of fibroma, complete responses were seen in 30% of cases at 3 or 6 months. More than twofold decreases in size were noted for the uterus and myomas in 54% of cases at 6 months. No response was found in eight (16%) patients, six of whom were obese. Complete remission of cysts was noted at 3 months in all six cases of polycystic ovary.

Laparoscopy indicated that when ovarian endometriosis was associated with mastopathy, it responded to treatment in two cases after 6 months.

Long-term follow-up. All patients were seen regularly, twice a year. After a mean of 2½ years of follow-up, we have been able to assess mammary and gynecologic relapse. Menstruation returned after cessation of treatment in all patients who had had regular cycles: 75 days after the last injection in 40 patients and 3 months later in 18 patients. No mammary relapse was noted, but some nodules and block recurred. Among the patients with complete response, the lesions reappeared (nodules, 2/6; block, 5/12; cysts, 6/12) but less frequently than in the group of patients with partial response (nodules, 15/36; block, 11/22). It is noteworthy that during this period no aggravation of the mastopathy was observed. Therefore, if the lesions recur, their number and size always remain smaller than before treatment. Among the patients with clinical symptoms, complete response remained without relapse in 50% of cases (15/32). This long-term response rate is also observed in the group of patients with partial response (15/30).

This suggests that [D-Trp⁶]-LHRH has a lasting effect in some cases. Follow-up therapy could be considered in other patients.

Uterine fibromas recurred sooner, and the increase in size was estimated to be 65% (31 cases) for all types of fibroma after a mean of 2½ years of follow-up.

Side effects. Hot flushes were reported by 64 patients (97%) and increased with time of treatment. Only 30% of these patients responded to additional nonhormonal treatment. Asthenia developed with time, was always present at 6 months, and responded best in 90% of cases to adjuvant vitamin B treatment. Forty of the 66 patients (60%) reported cephalalgia, which decreased with time and responded to additional therapy. Other manifestations (depression, vaginal mucous atrophy, decreased libido, visual disorders, hypertension) were relatively rare (4.6% of cases) and well tolerated. A flareup effect was seen in 18 patients (27%) 10 to 15 days after the first injection. This was due to drug-induced stimulation of the pituitary gonadal axis at the start of treatment and was marked by recurrence of mastodynia or onset of metrorrhagia. These manifestations were mild and generally subsided before the second injection of the analog. Providing that a partial response had been achieved with [D-Trp⁶]-LHRH (10/12), synergism was seen when tamoxifen was used as an adjunctive drug. No estrogenic effect of tamoxifen was seen. In two cases the inhibitory effect of

[D-Trp⁶]-LHRH was nullified by the clomiphene-like stimulatory effect of tamoxifen. Metrorrhagia, leukorrhagia, and ovarian cysts developed in these two cases, indicating that the suppressing effect of [D-Trp⁶]-LHRH had been counteracted by peripheral estrogen-like activity induced by tamoxifen. Combination therapy with [D-Trp⁶]-LHRH and cyproterone acetate was well tolerated, and synergism was seen in all cases (9/9). The gynecologic side effects (metrorrhagia) of cyproterone acetate were counteracted by the estrogen-depriving activity of [D-Trp⁶]-LHRH.

Comment

This is the first report of the use of an LHRH analog in the treatment of chronic mastopathy. In our study true or relative hyperestrogenism before treatment was noted in 30% of patients and overt hyperprolactinemia was present in 18%. Hormone receptors were present in 54% of patients, and 44% of patients were classified as estrogen receptor positive.

Although LHRH analogs are effective in most cases of severe mastopathy, their mechanism of action is incompletely understood. LHRH analogs act mainly by creating a state of estrogen deprivation, but it has also been suggested that they block ovarian steroidogenesis.[14]

Estrogens,[15] progesterone,[6] androgens,[16] and prolactin[17] influence cellular proliferation in the mammary gland in vitro. This action is mediated by the corresponding receptors, all of which are found in potentially malignant tissue. It has been shown in this study, and by other investigators, that in proliferative mastopathy estrogen receptors are correlated with the degree of epithelial hyperplasia[10] and cellular atypia and that progesterone receptors are correlated with the extent of stromal proliferation. The potent antigonadotropic action of LHRH agonists induces complete ovarian inhibition, which results in very low blood levels of estradiol, progesterone, ovarian androgens, and prolactin, in turn as a result of decreased blood estradiol. This indirect effect of high doses of LHRH analogs has been reported in premenopausal metastatic breast cancer, in which chemical castration gives significant results in 30% to 40% of cases.[8] In the present study, however, complete response to [D-Trp⁶]-LHRH alone was noted in only 27% of cases of estrogen receptor–positive mastopathy, 25% of which were atypical, indicating that the decrease in blood estradiol was not adequate to control the process and reverse the course of the disease.

In the normal breast estrogen receptors are present only at low levels in the first phase of the cycle.[12] In this study, with most patients not having luteal impairment, the presence of hormone receptors at day 20 of the menstrual cycle may indicate a possible disturbance of genomic regulation of estrogen receptors, the production of which may be independent of the hormonal cycle. This has been reported in breast cancer[18] but with more elevated levels of estrogen receptor than in proliferative mastopathy. It is also possible that local estrogens produced from androgens sustain to some extent the trophic function of the mammary gland (estrogen receptor), as has been suggested for the normal breast in menopausal women.[12]

In the second 3-month treatment period, synergistic action of the inhibitory agents tamoxifen and cyproterone acetate was related to the receptors found and was noted in 60% of hormone receptor–positive patients showing complete response (4/32) or partial (>60%) response (15/32). The synergism noted with tamoxifen was correlated mainly with estrogen receptor–positive cases, in which cellular atypia was often present. Other authors[19] have related a synergistic effect of the two drugs in estrogen receptor–negative breast carcinoma. Strong blocking of the ovary and pituitary ensured good drug safety and helped eliminate the clomiphene-like effects of tamoxifen and cyproterone acetate–induced metrorrhagia. Ovarian hyperstimulation was seen in only one of 12 patients receiving [D-Trp⁶]-LHRH and tamoxifen concomitantly.

Although hypophysial antagonism of the two drugs has been described,[8] it is rare with high doses of long-acting LHRH analogs. Although the hormonal mechanisms clearly exist, there are nonetheless some cases of mastopathy in which no endocrinologic disorders are

observed[3] and no increase in hormonal receptor content is found. In this study more than half the patients had normal hormone levels and were classified as estrogen receptor negative.

The best results with [D-Trp^6]-LHRH alone were seen in estrogen receptor–negative, progesterone receptor–negative patients (complete response in 71% of cases), characterized by glandular hyperplasia and the absence of cellular atypia. However, immunohistochemical determination showed that receptors could be present in some cases in this group.[10] The mechanism of action of LHRH analogs in hormone-independent groups is unknown. A strong effect in this subgroup of patients suggests that the drug may act directly. Direct in vitro action of LHRH analogs has been reported in breast cancer lines.[20] They inhibit the growth of MCF-7 cells, particularly when primed by estradiol. High-affinity LHRH receptors have been identified in various human mammary cancer lines[21] and in 260 of 500 biopsy specimens of human breast cancer.[22] However, receptors identified in some extrahypophysial tissues (testis, placenta) generally seem to display low affinity for LHRH agonists. The antiproliferative action of LHRH analogs on mouse mammary gland cells may be greater than that of ovariectomy. A direct antiproliferative action is supported in a study of the effects of in vivo administration of LHRH analog to mice on subsequent in vitro proliferation of MXT mammary tumor cell cultures (containing estrogen and progesterone receptors).[23] LHRH analogs are effective in postmenopausal women with breast cancer in whom blood estrogen levels are not affected (10% to 25% of cases). LHRH agonists also show some activity in premenopausal and postmenopausal estrogen receptor–negative breast cancers.[8, 24]

We used a quantitative autoradiographic analysis to study 20 cases of proliferative mastopathy. This technique permitted us to localize LHRH receptors in brain and in human ovaries.[13] We found that the receptors were present in 12 cases, but these binding sites were mainly of low affinity. Various explanations have been advanced to resolve the discrepancy between the marked in vitro and in vivo antiproliferative effects of LHRH agonists and their low affinity for receptors. It is possible that high concentrations of LHRH analogs have a biologic effect on weak cellular response, as seen in the placenta. The mitogenic action of the pituitary gonadotropins follicle-stimulating hormone and luteinizing hormone[23] is suppressed in the presence of LHRH analogs. However, this has not been verified in human breast cancers. We have noted a frequent association among proliferative mastosis, family history of breast cancer, and uterine fibroma. The risk for breast cancer seems to be increased by this clinical association in these diseases, which is sensitive to treatment with LHRH analogs.[7] The risk of malignancy linked to the first two factors and the beneficial effects of LHRH analogs on fibroma are already well known.[25] Our demonstration of the efficacy of these analogs in the treatment of high-risk benign mastopathy should help in the assessment of the therapeutic efficacy of this drug. As in the case of mastopathy, uterine fibromas are influenced by estrogen levels and have LHRH receptors.[26] However, mastopathy does not always involve increases in estrogen receptors. Antiestrogenic agents do not give such consistent results with major mastosis and fibromas as those that can be obtained with LHRH analogs, alone or in combination therapy. Tamoxifen was ineffective in one third of the cases in our study. Proliferation of mesenchymal cells (smooth muscle of the uterus, breast myoepithelium) is common in high-risk mastopathy and uterine fibroma. This was particularly evident in mastopathy with block, which was resolved by treatment with [D-Trp^6]-LHRH in 50% of cases in this study. There is an important fibromatous component in all cases of mastopathy. Its role in breast oncogenesis has been reported.[7] A harmonious interaction between the stroma and epithelial cells is required for tissue homeostasis. Myoepithelial cells play an important role in the development of breast cancer, as indicated by their special role in the basal membrane, their lack of estrogen receptors[10] and LHRH receptors, and their ability to secrete various endogenous growth factors.

In hormone-independent mastopathy, LHRH agonists may act at the stroma, which generally does not contain hormone receptors. However, it is not known if the initial trigger for cellular proliferation is associated with stromal proliferation or is induced by hormone-sensitive glandular cells. Fibrous proliferation does not reflect cicatrization but does indicate the presence of an active tumor, which regresses when the inducing stimulus is removed.[16] The role of fibrosis in oncogenesis has been demonstrated in many tissues, and interactions between stromal and glandular cells have been reported.[27] In mastopathy, LHRH analogs seem to control mesenchymal proliferation and thus could affect tumoral growth factors. Further studies are needed to confirm this and to define the effect of LHRH analogs on the epithelium and stroma.

In conclusion, high-risk fibrocystic mastopathy, particularly when associated with uterine fibroma, can be successfully treated by LHRH analogs in premenopausal women. Although these analogs improve clinical and radiologic manifestations of mastopathy, it remains to be seen whether they control epithelial proliferation at the subclinical stage. It is also necessary to determine the short- and long-term effects of estrogen deficiency. A short treatment (4 to 6 months) can control the progress of the disease without serious effects on bone density and gives better long-term results with mastopathy

than with fibroma. Larger scale within-subject studies are necessary to confirm the high risk present in this population (proliferative mastopathy, family history of cancer or uterine fibroma) and to establish whether breast cancer prevention by treatment with LHRH analogs is possible in these cases.

We wish to thank Drs. B. Schatz, J. Latouche, J.F. Morere, J. Aguillera, F. Khon, R. Edelstein, and M. Crepin for their collaboration, and Laboratoires Ipsen-Biotech for their technical help and the supply of [D-Trp^6]-LHRH.

Fast-scan magnetic resonance imaging in fetal visualization

Anne S. Garden, MB, ChB,[a] Richard D. Griffiths, MD,[b] A. Michael Weindling, MD,[c] and Peter A. Martin, PhD[d]

Liverpool, United Kingdom

Magnetic resonance imaging has potential as an imaging technique in obstetrics. Its application has been limited by the amount of image degradation that occurs as a result of fetal movement during the long imaging times. By use of a fast-scan imaging technique good images are obtained of fetal anatomy in 3 to 14 seconds per image, depending on the setting used. Different organs could be visualized by varying the setting. Magnetic resonance imaging complements the role of ultrasonography in fetal visualization. It also allows clear fetal imaging in such high-risk situations as maternal obesity and oligohydramnios, where it may be difficult to produce clear images by ultrasonography. This technique will allow wider application of magnetic resonance imaging in obstetrics and give additional information about the developing fetus. (Am J Obstet Gynecol 1991;164:1190-6.)

Key words: Magnetic resonance imaging, fast-scan technique, fetal visualization, fetal movement, fetal anatomy

Accurate fetal imaging is an essential part of feto-maternal medicine. Obstetric imaging techniques should be safe, noninvasive, and capable of providing good tissue definition in both normal and abnormal pregnancies.

Magnetic resonance imaging (MRI) fulfills these criteria. Its application to obstetrics has, however, been limited because of long imaging times. Conventional spin-echo nuclear magnetic resonance requires imaging times of 5 to 45 minutes[1] to produce a series of images. As each image is built up throughout this time, fetal movement causes distortion of the whole series. Fetal movement can be seen on ultrasonographic ex-

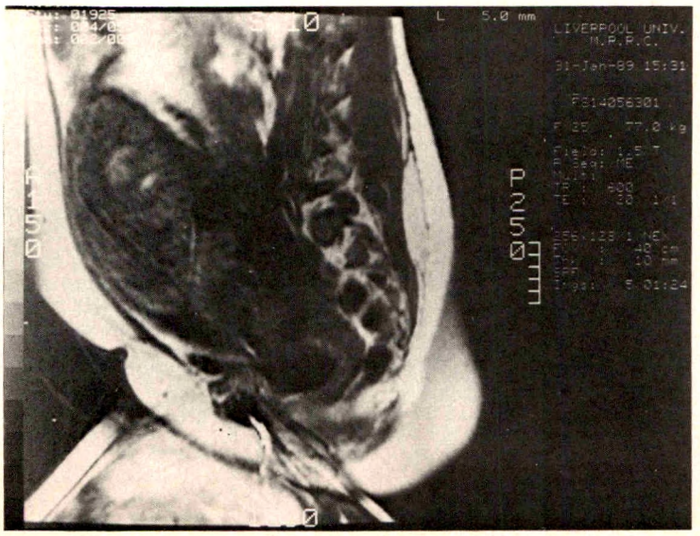

Fig. 1. Conventional spin-echo magnetic resonance imaging (repetition time, 600 msec; echo delay time, 20 msec) with complete loss of fetal visualization because of motion of nuclei.

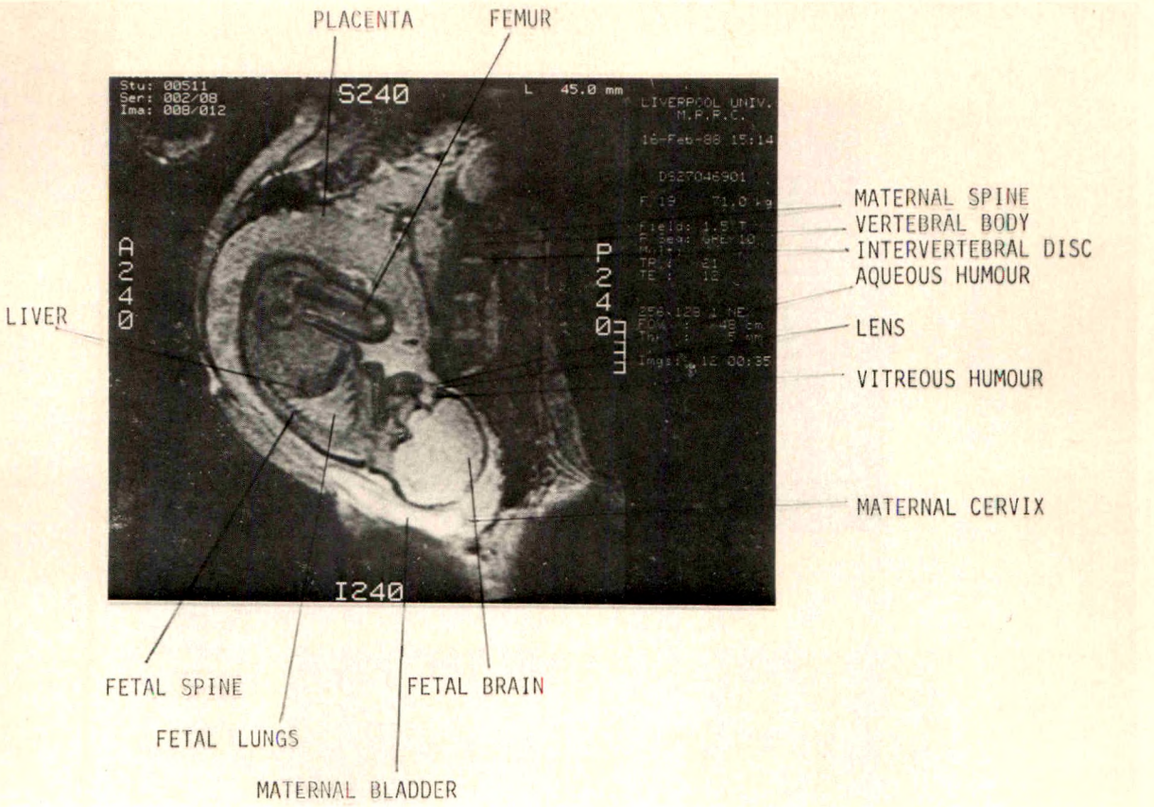

Fig. 2. Repetition time, 25 msec; echo delay time, 12 msec; flip angle, 10 degrees. Fetal anatomy clearly seen, including fetal lung, liver, brain, bone, and subcutaneous tissues.

amination from 7 weeks' gestation and becomes more frequent and complex with advancing gestation. Even at term gross body movements occur. Such fetal movements cause image degradation with MRI. Further distortion also occurs because of the movement of amniotic fluid nuclei. The combination of these two phenomena may cause such a degree of distortion as to give the appearance of an empty uterus. Almost all researchers in the field quote fetal movement as the main problem to be overcome and have limited its application in the study of growth and development of fetal organs. Administering benzodiazepine to the mother[2] or curare to the fetus[3] has been suggested as a means of reducing fetal movement. This is unacceptable for routine use, particularly with a technique that is otherwise noninvasive.

We describe a new application of a fast-scan imaging technique[4, 5] that is aimed at extending the use of MRI in obstetrics and facilitating the study of the developing fetus.

Conventional spin-echo MRI involves the application of a 90-degree radio-frequency pulse to the magnetic field. Time must be allowed between each excitation for the magnetic field to recover. This interval, the repetition time, is generally between 500 and 2000 msec. For the acquisition of reasonable images, the radio-frequency pulse must be repeated many times, and so a long repetition time results in relatively long imaging times. In fast-scan MRI a radio-frequency pulse that causes only a small excursion in the magnetization is applied. In this way the length of time taken to obtain an image can be shortened to a few seconds. Clearer fetal images are produced because of reduced movement artifact but at the expense of reduced signal strength. An additional advantage is that movement occurring during imaging causes distortion of only that single image in the series.

Patients and methods

A General Electric Signa system was used. Imaging was performed at 1.5 T with the standard body coil within the guidelines laid down by the National Radiological Protection Board in 1983.[6] Ethical permission was obtained from the local and regional scientific committees.

Sixty-seven women were recruited for the study from the antenatal clinics and wards. Twelve pregnancies were studied on two occasions. The studies were carried

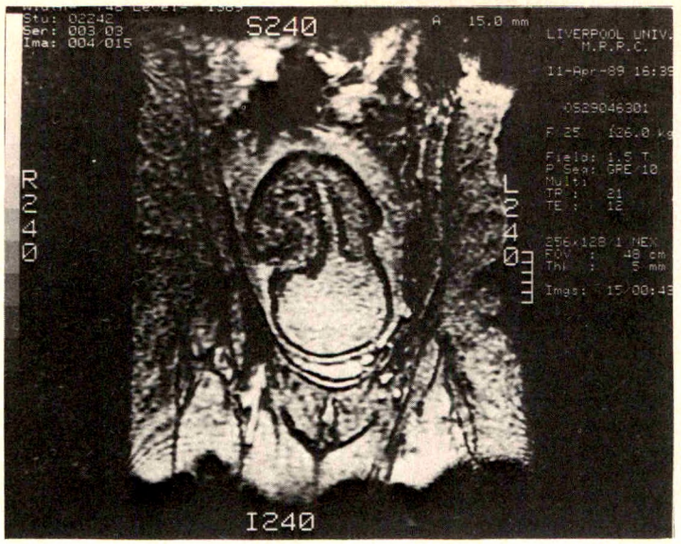

Fig. 3. Visualization of fetal brain and cervical spine in obese mother weighing 126 kg.

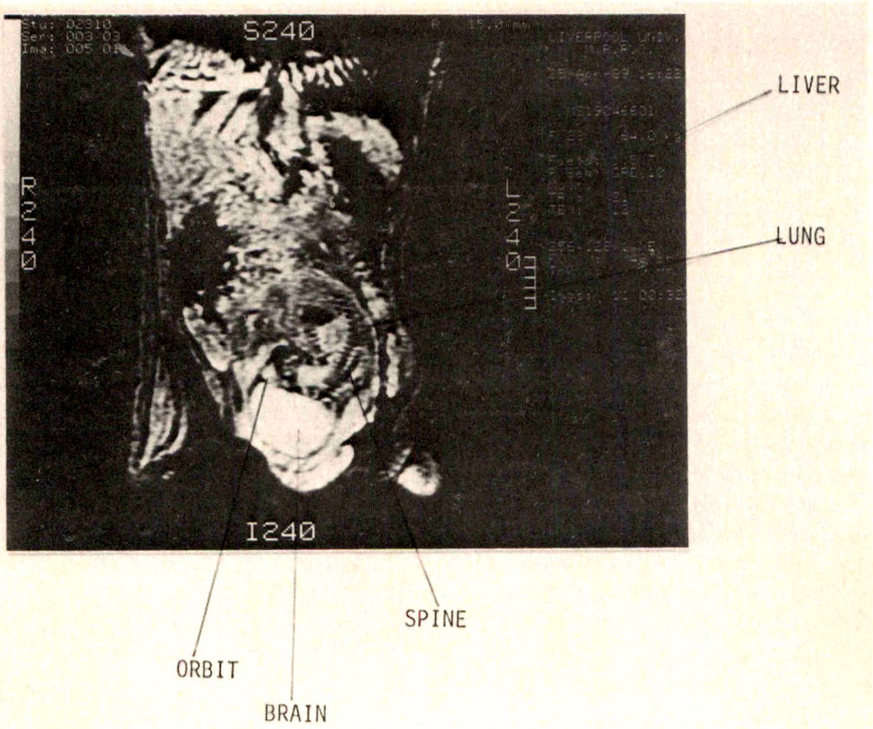

Fig. 4. Premature rupture of membranes at 30 weeks' gestation. Fetal anatomy including brain, vertebrae, lungs, and orbit seen despite lack of amniotic fluid.

out between 28 and 40 weeks' gestation. Forty-two of the women studied had uncomplicated pregnancies, and the remaining 25 gestations were complicated. Complications included suspected congenital anomalies (eight patients), polyhydramnios (three patients), medical disorders complicating the pregnancy (three patients—insulin-dependent diabetes in two and hemochromatosis in one), placenta previa (two patients),

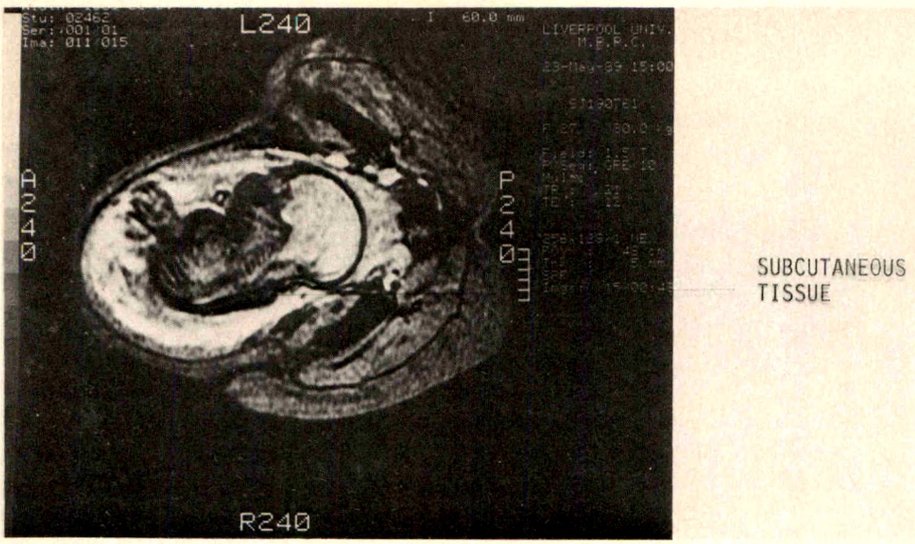

Fig. 5. Increased thickness of subcutaneous tissue in macrosomic baby of insulin-dependent diabetic mother.

suspected intrauterine growth retardation (two patients), prolonged premature rupture of the membranes with subsequent oligohydramnios (three patients), suspected macrosomia (two patients), and twin pregnancy complicated by intrauterine death of one twin (two patients).

With the fast-scan technique, imaging was carried out with the woman lying in the right lateral position. Foam padding was used to support the pregnant uterus and to maintain the woman's position comfortably within the magnet bore.

Initial fetal localization was carried out in the maternal axial, sagittal, and coronal planes. From these, fetal alignment could be ascertained and further imaging carried out in planes that gave optimum fetal visualization. Images were obtained at varying echo delay time, repetition time, and flip angles to assess the best settings for visualizing the fetal anatomy.

Results

No serious adverse effects were encountered. Three patients felt slightly claustrophobic on first entering the magnet bore but were able to continue with the study after assurance. Only one study had to be abandoned because of this.

With the conventional spin-echo settings, it was not possible to consistently and reliably image the fetus. On most occasions the appearance of an empty uterus was obtained (Fig. 1).

The best views of the fetus were considered to be those in which fetal organs could be easily identified. With a short repetition time of 25 msec, a short echo delay time of 12 msec, and a flip angle of 10 degrees, the fetal heart, liver, lungs, and bone were clearly seen (Fig. 2) and a clear outline was obtained of the fetal skin and subcutaneous tissue. With this setting, good visualization could be obtained in all clinical situations, including maternal obesity (Fig. 3) and oligohydramnios (Fig. 4). It also allowed measurement of the fetal subcutaneous tissue as an indicator of macrosomia (Fig. 5). A single image with this setting could be obtained in 3 seconds.

Similar echo delay time (12 msec) and repetition time (25 msec) but with a larger flip angle of 45 degrees, showed the anatomy less clearly but the fluid in the fetal bowel and umbilical cord was more distinct (Fig. 6). Clearer visualization of fluid in the fetal heart, vessels, and bowel (Fig. 7) was obtained with a repetition time of 100 msec, echo delay time of 12 msec, and flip angle of 60 degrees. This setting, however, required 14 seconds to acquire a single image that consequently increased image distortion because of movement.

A repetition time of 100 msec, echo delay time of 30 msec, and a flip angle of 30 degrees produced strong signals from the brain (Fig. 8). A single slice was obtained in 13 seconds.

The peak specific absorption rate for radiofrequency exposure in these studies ranged from 0.017 W/kg for the faster settings to 0.105 W/kg for the slower settings required for the studies of the intracranial anatomy.

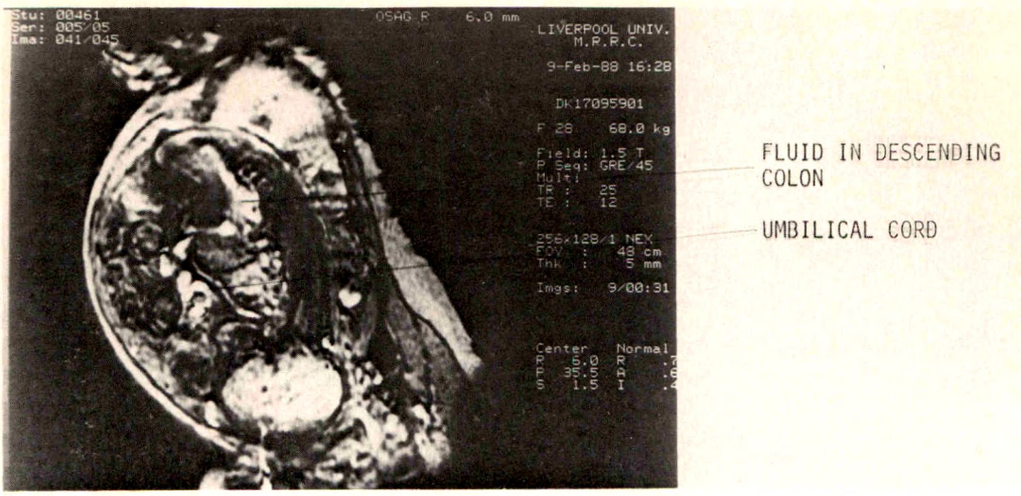

Fig. 6. Repetition time, 25 msec; echo delay time, 12 msec; flip angle, 45 degrees. Fetal anatomy less distinct than in Fig. 1, but fluid in descending colon and umbilical cord clearly visible.

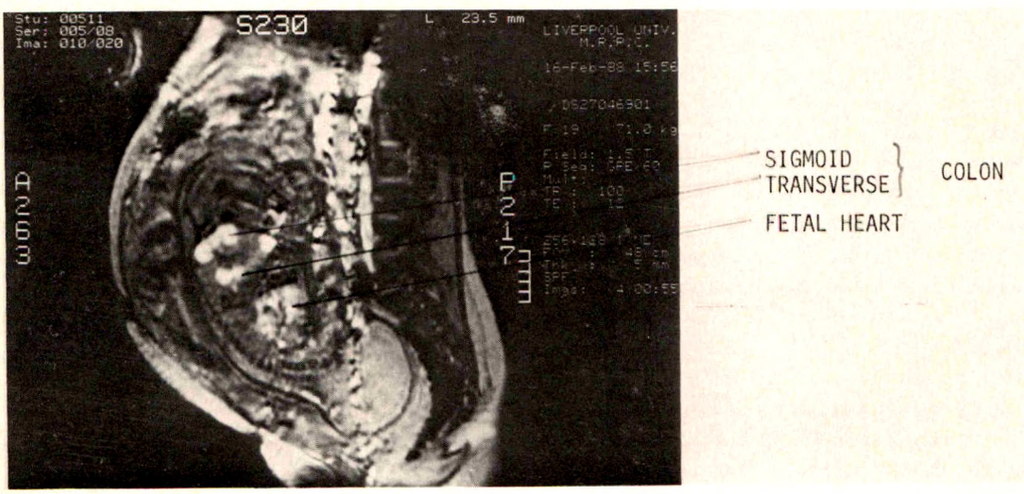

Fig. 7. Repetition time, 100 msec; echo delay time, 12 msec; flip angle, 60 degrees. Fetal anatomy less distinct than in Fig. 2, but fluid in bowel and fetal heart visible. Artifact caused by flow in maternal vessel.

Comment

The safety of MRI has been considered in many studies. Biomedical investigation by means of bacteria or cell culture, in vivo studies, and clinical follow-up of patients has failed to identify any adverse effects.[7-10] Three specific areas have been considered by the National Radiological Protection Board—the effects of the static magnetic field; the time-varying magnetic field effect, which may cause the induction of electric currents; and heat production by the radio-frequency magnetic fields. The guidelines laid down by the board are aimed at preventing these potential hazards.[6] McRobbie and Foster[11] in a study of pregnant mice showed no significant difference between the litter numbers and growth rates of the exposed litters compared with controls. However, the National Radiological Protection Board has advised against imaging during the first trimester, i.e., the period of organogenesis, unless the patient is undergoing termination of pregnancy.

The peak specific absorption rates obtained in this study of 0.017 to 0.105 W/kg are well within the limits

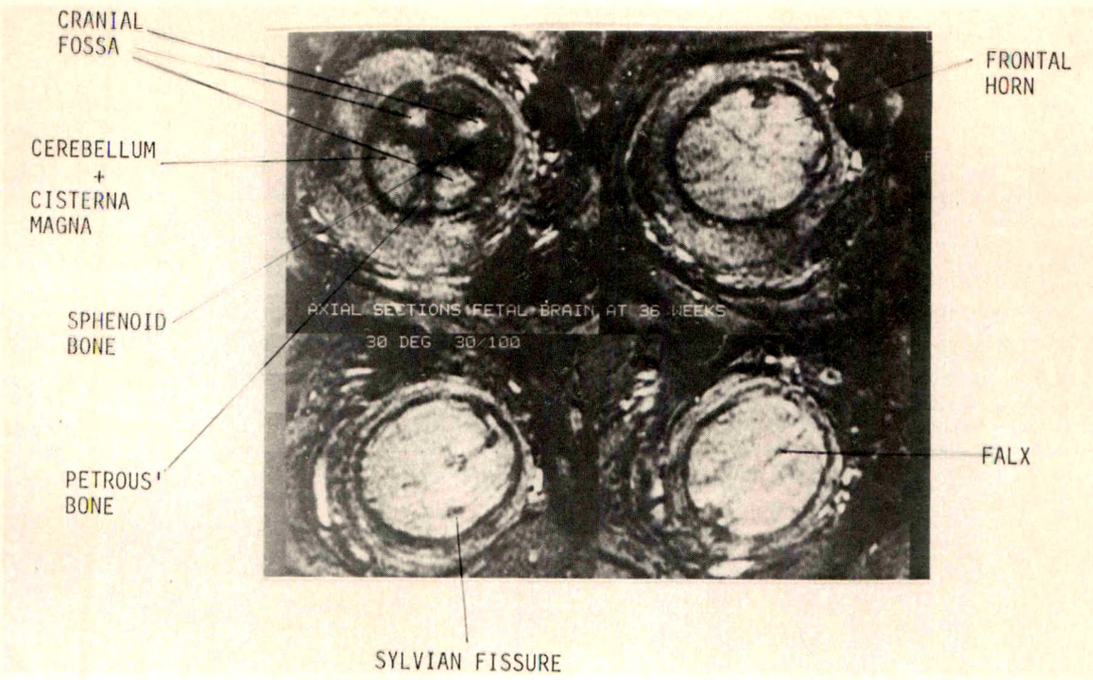

Fig. 8. Repetition time, 100 msec; echo delay time, 30 msec; flip angle, 30 degrees. Detail of intracranial anatomy seen.

laid down by the National Radiological Protection Board[6] and compare favorably with the spin-echo study peak specific absorption rates of 0.577 W/kg.

Other studies with the conventional spin-echo technique have shown that MRI has potential in obstetric imaging.[12, 13] Long imaging times, however, have limited its application. The fast-scan technique described here overcame that problem.

Clearer images are obtained by reduction in motion artifact, and, in addition, the short imaging time allowed image alignment so that fetal anatomy could be visualized by design rather than fortuitously. Other workers in the field have commented on the difficulty of doing this with the conventional spin-echo technique.[14] Using the fast-scan technique, we have been able to image, in every patient studied, the fetal brain, spinal cord, skeleton, lungs, heart, liver, limbs, subcutaneous tissue, and placenta. Details of intracranial anatomy and kidneys have been less consistently visualized. Clear images were also obtained in patients with oligohydramnios or maternal obesity. Ultrasonographic images obtained in these situations give poor image definition.

A further benefit was that the maternal position could be maintained without difficulty within the magnet bore. This has been found to be a problem with the long imaging times required for conventional scanning.[15]

MRI, in contrast to ultrasonography, cannot be used at the bedside nor does it give real-time images. Echo-planar MRI is being developed[16, 17] and has great potential. The image quality at present is not as good as that obtained by fast-scan MRI, however, and requires equipment that is not currently commercially available. The fast-scan imaging technique described here is suitable for all later generations of scanners currently available and installed in many hospitals.

Therefore MRI does fulfill the criteria for obstetric imaging. It is safe, noninvasive, and can be used in both normal and abnormal pregnancies. Although the expense of the unit and the current lack of a real-time facility prevent its superseding ultrasonography as the first-line obstetric imaging technique, it certainly has a complementary role. In particular, it gives superior soft-tissue images and may provide useful additional information about fetal growth and organ development.

The N-terminal and C-terminal portions of the atrial natriuretic factor prohormone increase during preeclampsia

Rhene W. Merkouris, MD,[a] Frank C. Miller, MD,[a] Val Catanzarite, MD, PhD,[a] J. Gerald Quirk, Jr., MD, PhD,[a] Lee A. Rigg, MD, PhD,[a] and David L. Vesely, MD, PhD[b]

Little Rock, Arkansas, and Tampa, Florida

The influence of preeclampsia on the circulating concentrations of the 28-amino-acid carboxy terminus (C-terminus) (i.e., atrial natriuretic factor) and the amino terminus (N-terminus) of the 126-amino-acid atrial natriuretic factor prohormone (pro ANF) was studied in the third trimester with the use of three specific radioimmunoassays that recognize: (1) atrial natriuretic factor (i.e., amino acids 99 to 126), (2) the whole 98-amino-acid N-terminus, and (3) amino acids 31 to 67 from the midportion of the N-terminus of the prohormone. The C-terminus was significantly increased ($p < 0.001$) in the third trimester in women with preeclampsia, the mean ± SEM of 15 subjects was 150 ± 7 pg/ml versus 89 ± 7 pg/ml in the third trimester in 12 women during normal pregnancies and 65 ± 2 pg/ml in 19 healthy nonpregnant women. The whole 98-amino-acid N-terminus, likewise, was significantly increased ($p < 0.001$) in women with preeclampsia to 4706 ± 629 pg/ml versus 2160 ± 79 pg/ml in women in the third trimester of normal pregnancies and versus the circulating concentration of 1847 ± 127 pg/ml in healthy nonpregnant women. ProANF 31 to 67 mean circulating concentration in preclampsia was 4638 ± 725 pg/ml, which was also significantly ($p < 0.001$) increased compared with its mean circulating concentration in the third trimester of normal pregnancy of 1758 ± 83 pg/ml or that in healthy nonpregnant women (1400 ± 105 pg/ml). The circulating concentrations of both the N-terminus and C-terminus of the atrial natriuretic factor prohormone decreased within 24 hours after delivery in contrast to a normal pregnancy in which they both increase post partum. These results indicate a marked difference in the metabolism of both the N-terminus and the C-terminus of the atrial natriuretic factor prohormone in women with preeclampsia versus that in women with normal pregnancies or that in healthy nonpregnant women. (AM J OBSTET GYNECOL 1991;164:1197-202.)

Key words: Preeclampsia, atrial natriuretic factor prohormone, proteinuria, hypertension, edema

Atrial natriuretic factor (ANF), the 28-amino-acid carboxy terminus (C-terminus) end of the 126-amino-acid ANF prohormone that is synthesized in cardiac myocytes, has natriuretic, diuretic, and potent vasodilator properties.[1] Recently, it has been found that peptides from the amino terminus (N-terminus) end of this prohormone, that is, amino acids 1 to 30 (pro ANF 1 to 30; long-acting sodium stimulator) and amino acids 31 to 67 (pro ANF 31 to 67; vessel dilator) also have vasodilatory,[2] natriuretic, and diuretic properties that are similar to ANF.[3] The vasodilatory effects of prohormone ANFs 1 to 30 and 31 to 67, as well as those of ANF (i.e., amino acids 99 to 126 of the prohormone) are associated with a fourfold to fivefold increase in cyclic guanosine monophosphate, which is due to activation of particulate guanylate cyclase (EC 4.6.1.2).[2] With the use of specific and sensitive radioimmunoassays the whole N-terminus of the ANF prohormone and a 3900 to 4000 peptide from the midportion of the N-terminus that is consistent with prohormone ANF 31 to 67 have recently been demonstrated to circulate normally in humans.[4-8]

Human ANF is found in increased concentrations in the blood of women with preeclampsia compared with the blood of normal pregnant women.[9, 10] Preeclampsia is not accompanied by the 40% plasma-volume expansion that is seen in a normal pregnancy.[11] Rather, preeclampsia is associated with increased generalized vasoconstriction.[12] This vasoconstriction is believed to cause an increased volume load to the cardiac atria which results in enhanced release of ANF into the circulation.[13] Since the N-terminus of the ANF prohormone is released simultaneously with physiologically induced central hypervolemia (i.e., "head-out-of-water" immersion),[14] the present investigation was de-

signed to compare the circulating concentration of the N-terminus of the prohormone in the circulation of women during pregnancies that are complicated by preeclampsia and again in these same women after delivery. This was done by utilization of sensitive and specific radioimmunoassays that recognize amino acids 1 to 98 and 31 to 67 of the ANF prohormone.

Patients and methods

Patients. Fifteen pregnant women between the ages of 16 and 34 years (mean ± SD = 24 ± 5 years) fulfilled the criteria for preeclampsia of (1) a diastolic blood pressure > 90 mm Hg and (2) excretion of > 1 gm of protein per day.[15] Their blood pressures ranged from 136/98 mm Hg to 180/120 mm Hg with a mean of 156/107 mm Hg; heart rates ranged from 72 to 96 beats/min (mean, 85 ± 7) (Table I). Two of the preeclamptic patients (nos. 2 and 10) had a documented history of hypertension that antedated these pregnancies. They were receiving methyldopa, labetolol, hydralazine, and Aldactazide when they were admitted because of preeclampsia; the other 13 patients were not receiving any medication except iron and vitamin supplements. All women were admitted to the maternity unit of the University Hospital of Arkansas at least 2 days before the study was performed. The preeclamptic women consumed a diet of 120 mEq/day of sodium while they were in the hospital. They all had activity limited to bed rest with bathroom privileges. No medications were given for 24 hours before or during the study. Gestational age was estimated by obstetric history and confirmed by fetal ultrasonography. The amount of proteinuria was evaluated by the dipstick method in which 1+ = 30 mg/dl, 2+ = 100 mg/dl, 3+ = 300 mg/dl, and 4+ = 2000 mg/dl protein. During labor all of the preeclamptic subjects received intravenous magnesium sulfate, and eight subjects (1, 2, 5, 8, 9, 10, 14, 15) were given hydralazine to control blood pressure during labor or delivery or during the first 24 hours after delivery.

All plasma samples that were to be assayed for the C-terminus and the N-terminus of the ANF prohormone were obtained from the antecubital vein while each subject was in a sitting position. Informed consent was obtained from each of the 15 volunteers with preeclampsia after the nature and possible consequences of the study were fully explained. This investigation was approved by the Human Use Committee of the University of Arkansas for Medical Sciences.

Methods. Radioimmunoassays to measure the N-terminus of the prohormone were devised to amino acids 1 to 30 and 31 to 67 of the 126-amino-acid prohormone; the C-terminus assay recognizes amino acids 99 to 126 of the prohormone, that is ANF as previously described by our laboratory.[4-8] Gel-permeation chromatography with G-50 Sephadex revealed that the prohormone ANF 1 to 30 radioimmunoassay recognizes a peptide of 10,000 molecular weight which is consistent with the whole N-terminus (i.e., amino acids 1 to 98 of the prohormone) but lacks the C-terminus (i.e., ANF).[8] Thus although the prohormone ANF 1 to 30 radioimmunoassay was devised to recognize synthetic amino acids 1 to 30 of the 126-amino-acid prohormone, it immunologically recognizes the whole 1 to 98 amino acid segment that makes up the N-terminus of the prohormone. The prohormone ANF 31 to 67 radioimmunoassay, on the other hand, recognizes a peptide of 3900 to 4000 molecular weight from the midportion of the N-terminus of the prohormone (actual ANF prohormone 31 to 67 molecular weight = 3878).[8] Similarly,

Table II. N-terminus (i.e., amino acids 1-98), midportion of N-terminus (i.e., pro ANF 31-67), and C-terminus (ANF) of ANF prohormone in preeclampsia

Nonpregnant (n = 19) (mean ± SEM)	1847 ± 127		1400 ± 105		62 ± 5	

*Circulating concentrations of pro ANF 1 to 98, pro ANF 31 to 67, and ANF in women with preeclampsia significantly increased ($p < 0.001$) when compared with the circulating concentration of these peptides in nonpregnant women when evaluated by one-way analysis of variance.

†The circulating concentrations of pro ANF 1 to 98, pro ANF 31 to 67, and ANF decreased significantly ($p < 0.001$) 24 hours after delivery compared with the predelivery preeclamptic concentrations when evaluated by paired Student's t test.

G-50 Sephadex gel permeation chromatography revealed that the ANF radioimmunoassay recognizes a peptide of approximately 3000 molecular weight, and the actual molecular weight of ANF is 3081.

Blood samples were placed in 5 ml EDTA (ethylenediaminetetraacetic acid) tubes and immediately centrifuged at 3000 g for 15 minutes. After centrifugation, the plasma was extracted with 100% ethanol (1:1 dilution), mixed by vortexing, and allowed to stand at 4° C for 30 minutes. After 30 minutes at 4° C, the samples were centrifuged at 3000 g for 15 minutes, and the supernatants were dried via controlled nitrogen flow. The samples were then ready for radioimmunoassay. All determinations were performed in triplicate. The intraassay coefficient of variation for prohormone ANFs 1 to 30, 31 to 67, and ANF radioimmunoassays were 4.8%, 5.3%, and 5.7%, respectively. The interassay coefficient of variation was 8% for both prohormone ANFs 1 to 30 and 31 to 67 radioimmunoassays, whereas the interassay variation of ANF was 6.9%. Recovery was examined by the addition of synthetic unlabeled prohormone ANF 1 to 30, prohormone ANF 31 to 67, and ANF at 100, 200, and 400 pg/ml to pooled plasma. Recovery (mean ± SD) for prohormone ANF 1 to 30 was 83.5% ± 13.2% and for prohormone ANF 31 to 67 recovery was 100.9% ± 8.9%. Recovery of ANF was 92% ± 11%. The respective 50% inhibitory concentrations were 180, 120, and 11 fmol per tube whereas the lowest detectable concentrations were 40, 35, and 1.4 fmol for prohormone ANFs 1 to 30, 31 to 67, and ANF radioimmunoassays, respectively. Serial dilution of pooled plasma has revealed excellent parallelism of the standard and the unknown in these assays.[5, 8]

Statistical analysis. All values are reported as mean ± SEM. Differences between groups were analyzed by one-way analysis of variance. The differences between samples in the same individual were evaluated by Student's t test for paired data.

Results

The circulating concentrations of each of the ANF prohormone peptides were significantly elevated ($p < 0.001$) in blood that was obtained from the pregnant women with preeclampsia compared with concentrations in nonpregnant women (Table II). Specifically, the mean concentration of the whole N-terminus (4706 ± 629 pg/ml) in the 15 women with preeclampsia was two times higher than mean blood concentrations in 19 healthy nonpregnant women who had concentrations of 1847 ± 127 pg/ml.[4] The midportion of the N-terminus, which consists of amino acids 31 to 67 of the ANF prohormone (i.e., prohormone ANF 31 to 67), in women with preeclampsia was three times higher than its mean circulating concentration in 19 nonpregnant women (4638 ± 725 pg/ml vs 1400 ± 105

pg/ml).[4] The C-terminus (i.e., ANF) of the ANF prohormone was two times higher in women with preeclampsia than in healthy nonpregnant women (Table II).

This mean concentration of the N-terminus in the third trimester of pregnancy with preeclampsia was also significantly higher ($p < 0.001$) than its mean circulating concentration of 2160 ± 79 pg/ml in 12 women during the third trimester of normal pregnancy.[16] The mean concentration of prohormone ANF 31 to 67 in the third trimester was also significantly higher ($p < 0.001$) than its circulating concentration of 1758 ± 83 pg/ml in 12 women during the third trimester of normal pregnancy.[16] The mean circulating concentration of the C-terminus was nearly two times higher than its mean circulating concentration of 89 ± 7 pg/ml in 12 women during the third trimester of normal pregnancy.[16]

The circulating concentration of the whole N-terminus, the midportion of the N-terminus, and the C-terminus of the ANF prohormone correlated roughly with the severity of the preeclampsia. The subject with the mildest preeclampsia (No. 3 in Table I) had the lowest circulating concentrations of the N-terminus, prohormone ANF 31 to 67, and the C-terminus, whereas two of the subjects with the most severe preeclampsia (No. 9 and No. 10 in Table I), on the basis of severity of hypertension and amount of proteinuria, had two of the highest circulating concentrations of these peptides. Two other subjects with severe preeclampsia as determined by amount of proteinuria (Nos. 5 and 8 in Table I) also had very high circulating concentrations of the whole N-terminus, prohormone ANF 31 to 67, and ANF. One patient with severe preeclampsia (No. 14), however, did not have as high a circulating concentration of these peptides as did the other subjects with severe preeclampsia, although this subject's (No. 14) circulating concentrations of all three peptides were twice that of women in the third trimester of normal pregnancies. Thus in general, the circulating concentration of all three of these peptides correlated with the severity of the preeclampsia.

After delivery, the levels of the whole N-terminus, the midportion of the N-terminus, and the C-terminus of the ANF prohormone decreased significantly ($p < 0.001$) within 24 hours (Table II). Although the levels of the N-terminus, prohormone ANF 31 to 67, and ANF did not decrease completely into the normal range for all women with preeclampsia during this time period, in every preeclamptic subject there was a marked decrease after delivery. In general, the subjects with the highest circulating concentrations of these peptides were those who did not attain the circulating concentration of a nonpregnant person within 24 hours. It is important to note that in some persons with severe preeclampsia such as subject No. 5, the circulating concentrations of the C-terminus returned to the upper levels of the normal range within 24 hours, whereas the whole N-terminus and the midportion of the N-terminus (i.e., prohormone ANF 31 to 67) were still significantly ($p < 0.05$) elevated.

Comment

Although measured plasma volume is usually reported to be decreased in preeclampsia,[11, 17] there is a generalized increase in vasoconstriction as preeclampsia becomes more severe.[12, 17] This vasoconstriction causes an increased localized volume load to the cardiac atria, which results in enhanced release of ANF into the circulation.[13] In the present investigation, as in previous studies,[9, 10, 13] the level of ANF was found to be markedly increased in preeclampsia compared with the circulating concentration of ANF during a normal pregnancy. In addition to ANF (i.e., the 28-amino-acid C-terminus of the 126-amino-acid ANF prohormone), we found that the N-terminus of this prohormone increased in the plasma of women with preeclampsia compared with its circulating concentration in both normal nonpregnant[4, 8] and pregnant women[16] as determined by two sensitive and specific radioimmunoassays. One of these radioimmunoassays (i.e., prohormone ANF 1 to 30) immunologically recognizes the whole N-terminus of the prohormone (i.e., amino acids 1 to 98 of the prohormone), and the second N-terminal assay (prohormone ANF 31 to 67) recognizes a midportion of the N-terminus (amino acids 31 to 67).[8] Prohormone ANF 31 to 67 circulates in the blood as a distinct peptide with natriuretic properties[3] after it has been cleaved from the rest of the prohormone by proteases.[8] Although this is the first investigation that demonstrates a significant increase in the N-terminal portion of the ANF prohormone during preeclampsia, with the use of two separate assays, it appears that both the N-terminus and the C-terminus increase in the circulation of women with preeclampsia. Central hypervolemia does simultaneously release both the N-terminus and the C-terminus of the ANF prohormone,[14] but whether central hypervolemia is the cause or the result of the marked elevation of both the N-terminus and the C-terminus of the ANF prohormone in preeclampsia is uncertain at present.

If hypervolemia with an increased release of the N-terminus and C-terminus was the whole cause of the markedly increased circulating levels in preeclampsia, one might wonder, why in normal pregnancy with its marked increase in plasma volume, the levels of the N-terminus and the C-terminus of the ANF prohormone were not higher than preeclamptic levels.[16] The exact role of a localized volume load to the heart with in-

creased circulating concentration of the C-terminus and the N-terminus could not be ascertained from the present study.

The contribution of heart rate to the increased circulating levels of prohormone peptides also could not be determined with certainty from the present study. With cardiac pacing, however, the increased release of the N-terminus and the C-terminus of the ANF prohormone is not observed until the rate is 125 beats/min.[7] Since none of the women with preeclampsia had a heart rate above 96 beats/min, one would suspect that heart rate did not contribute significantly to the increased concentrations of the N-terminus and the C-terminus of the ANF prohormone in preeclampsia.

Another possible contributor to the increased concentrations of the N-terminus and C-terminus of the ANF prohormone may be the hypertension that is associated with preeclampsia. Atrial natriuretic factor is known to be increased in certain forms of hypertension such as the high blood pressure that is associated with essential hypertension,[18, 19] with pheochromocytomas,[20] and with the hypertension that is associated with obesity.[21] The hypertension that is associated with pheochromocytomas may be most similar to the hypertension that is associated with preeclampsia in that in both cases there is relatively decreased plasma volume and peripheral vasoconstriction.[22] The hypertension of preeclampsia is associated with increased circulating concentrations of the N-terminus and the C-terminus of the ANF prohormone, both of which decrease into the normal range when the pheochromocytomas are removed.[23] Thus at present it would appear that in both the subjects with preeclampsia and in women with pheochromocytomas, the major contributing factor to the increased release of the N-terminus and C-terminus of the ANF prohormone is the generalized vasoconstriction, which causes a local increased volume load to the cardiac atria, which, in turn, releases both the N-terminus and C-terminus of the prohormone. In a recent essay Easterling and Benedetti[22] have advanced the hypothesis that preeclampsia is a hyperdynamic disease process that is accompanied by increased cardiac output and vasodilation early in the disease with contracted intravascular volume and elevated systemic vascular resistance as it progresses. The present study, which evaluated 15 women with preeclampsia in the third trimester of their pregnancies is compatable with the latter part of this hypothesis in that the vasoconstriction is probably the main cause of the release of these peptides. The increased circulating concentrations of the N-terminus and the C-terminus of the ANF prohormone in the third trimester of pregnancy help to explain the relative hypovolemia,[11, 17] as well as the relative hyporeninemia and hypoaldosteronism,[22] since active atrial natriuretic peptides would decrease plasma volume by the induction of natriuresis and by interstitial shift of plasma.[1, 3] The C-terminus of the prohormone has also been shown to decrease plasma renin activity and aldosterone.[13]

Although the present study did not evaluate women with preeclampsia early in their pregnancies, if the N-terminus and the C-terminus of the ANF prohormone were increasing early as a result of increased cardiac output, they would cause vasodilation as hypothesized by Easterling and Benedetti[22] since both the N-terminus[3] and the C-terminus[1, 3] contain vasodilatory peptides. A future longitudinal study of the N-terminus and the C-terminus of the ANF prohormone early and throughout preeclamptic pregnancies will document whether an early increase in these peptides may mediate the early vasodilation that is suggested in the Easterling and Benedetti hypothesis of preeclampsia.[22]

The N-terminus, the midportion of the N-terminus (prohormone ANF 31 to 67), and the C-terminus all decreased within 24 hours of delivery in the 15 subjects with preeclampsia. This is in marked contrast to a normal pregnancy in which the C-terminus[24, 25] and the N-terminus[16] increase post partum. Although the reason for this difference between patients with preeclampsia and women who have normal pregnancies is unknown, it does point to possible altered metabolism of these atrial peptides in women with preeclampsia after delivery of the infant and the placenta, which suggests that the fetus and the placenta are not involved in this altered metabolism. Whether the postpartum differences between women with normal pregnancies and women with preeclampsia in the circulating concentrations of the N-terminus and the C-terminus of the ANF prohormone relate only to marked differences in predelivery plasma volume with increased plasma volume in a normal pregnancy and decreased plasma volume in preeclampsia could not be determined from the present investigation. It is probable, however, that part of the mechanism involves a decrease in generalized vasoconstriction at delivery in women with preeclampsia with a resulting decrease in central venous pressure that would result in a decreased release of the N-terminus and the C-terminus of the ANF prohormone. In women with normal pregnancies who do not have vasoconstriction to be released at delivery, there would not be the same stimulus to decrease central venous pressure, and their peptide levels, as mentioned previously, would increase rather than decrease.

In summary, the present study demonstrates that both the circulating concentrations of the N-terminus and the C-terminus of the prohormone of ANF increase in preeclampsia. This increase is greater than that seen in the third trimester of normal pregnancies. The present study also demonstrates that both the N-terminus and the C-terminus of the ANF prohormone

decrease after delivery. This is in marked contrast to normal pregnancies in which the C-terminus and N-terminus of the prohormone increase post partum.

covering the world

Organons extensive gynaecological product range is esteemed by the medical profession and by innumerable users throughout the world. Similarly, the organisation which develops and supports these products extends world wide. Today Organon includes more than 45 affiliated companies guaranteeing high standards of quality and service.

ORGANON IN GYNAECOLOGY

striving for completeness

Organon

Life companion

The rich tradition of gynaecological innovation by Organon research has recently been augmented in the field of hormone replacement therapy.
An entirely original medicine has been developed for the post-menopause.
This new therapy has been christened 'gonadomimetic'. Again this innovation demonstrates Organon's ability to lead the way in matching innovation with reliability.

memory

A lively and authoritative review of the year's best journal literature.

Let's face it. Remembering everything from the hundreds of articles you read is a herculean task. You're bound to forget a few important details. It's normal. It's healthy. But with a subscription to the *Year Book of Obstetrics and Gynecology*, it's also unnecessary.

Each year, the *Year Book of Obstetrics and Gynecology* brings you the most important articles relating to obstetrics and gynecology. The articles, chosen by our distinguished editors, are abstracted into concise one and two page summaries for quick and efficient reading. Nearly every article is accompanied by personal commentary from the editors discussing its significance to your daily practice.

The *Year Book of Obstetrics and Gynecology* — it's the best way to remember what you shouldn't forget.

A red spot means a lot to a woman.

A red spot may mean breakthrough

Tri-Levlen® means a low incidence of breakthrough bleeding/spotting*†

Multicenter study demonstrates significantly less breakthrough bleeding/spotting through the first six cycles[1]

P<0.05 for cycles 1,2,3, and 5[1]

n = number of women with a bleeding event occurring during a cycle.

TRI-LEVLEN®

Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

may mean a lot to a woman

* Incidence defined as percentage of women with a bleeding event occurring at least once during a pill cycle. Serious as well as minor side effects have been reported with the use of oral contraceptives. The physician should remain alert to the earliest symptoms of serious disease and discontinue oral contraceptive therapy when appropriate. Please see full prescribing information, a brief summary of which follows.

† Defined as intermenstrual bleeding.

BERLEX Dedicated to innovation in OB/GYN medicine

TRI·LEVLEN®

Levonorgestrel and ethinyl estradiol tablets–Triphasic regimen

TRI-LEVLEN® 28 TRI-LEVLEN® 21

BRIEF SUMMARY

Tri-Levlen®—6 brown tablets, each containing 0.050 mg of levonorgestrel (d(-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxygon-4-en-3-one), a totally synthetic progestogen, and 0.030 mg of ethinyl estradiol (19-nor-17α-pregna-1,3,5(10)-trien-20-yne-3, 17-diol); 5 white tablets, each containing 0.075 mg levonorgestrel and 0.040 mg ethinyl estradiol; 10 light-yellow tablets, each containing 0.125 mg levonorgestrel and 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day triphasic regimen).

Indications and Usage

Oral contraceptives are indicated for the prevention of pregnancy in women who elect to use this product as a method of contraception.

Contraindications

Oral contraceptives should not be used in women with any of the following conditions: thrombophlebitis or thromboembolic disorders, a past history of deep-vein thrombophlebitis or thromboembolic disorders, cerebral-vascular or coronary-artery disease, known or suspected carcinoma of the breast, carcinoma of the endometrium or other known or suspected estrogen-dependant neoplasia, undiagnosed abnormal genital bleeding, cholestatic jaundice of pregnancy or jaundice with prior pill use, hepatic adenomas or carcinomas, known or suspected pregnancy.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral-contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia, gallbladder disease, and hypertension, although the risk of serious morbidity or mortality is very small in healthy women without underlying risk factors. The risk of morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks. The information contained in this package insert is principally based on studies carried out in patients who used oral contraceptives with higher formulations of estrogens and progestogens than those in common use today. The effect of long-term use of the oral contraceptives with lower formulations of both estrogens and progestogens remains to be determined. Throughout this labeling, epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of disease, namely, a ratio of the incidence of a disease among oral-contraceptive users to that among nonusers. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide a measure of attributable risk, which is the difference in the incidence of disease between oral-contraceptive users and nonusers. The attributable risk does provide information about the actual occurrence of a disease in the population. For further information, the reader is referred to a text on epidemiological methods.

1. *Thromboembolic Disorders and Other Vascular Problems*

a. *Myocardial Infarction.* An increased risk of myocardial infarction has been attributed to oral-contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary-artery disease such as hypertension, hypercholesterolemia, morbid obesity, and diabetes. The relative risk of heart attack for current oral-contraceptive users has been estimated to be two to six. The risk is very low under the age of 30. Smoking in combination with oral-contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women in their mid-thirties or older with smoking accounting for the majority of excess cases. Mortality rates associated with circulatory disease have been shown to increase substantially in smokers over the age of 35 and non-smokers over the age of 40 among women who use oral contraceptives. Oral contraceptives may compound the effects of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see section 9 in "Warnings"). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors.

b. *Thromboembolism.* An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to nonusers to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep-vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the relative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease due to oral contraceptives is not related to length of use and disappears after pill use is stopped. A two-to four-fold increase in relative risk of postoperative thromboembolic complications has been reported with the use of oral contraceptives. The relative risk of venous thrombosis in women who have predisposing conditions is twice that of women without such medical conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and for two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and during and following prolonged immobilization. Since the immediate post partum period is also associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than four to six weeks after delivery in women who elect not to breast-feed, or a midtrimester pregnancy termination.

c. *Cerebrovascular diseases.* Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and nonusers, for both types of strokes, while smoking interacted to increase the risk for hemorrhagic strokes. In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for nonsmokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk is also greater in older women.

d. *Dose-related risk of vascular disease from oral contraceptives.* A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high-density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high-density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the nature and absolute amount of progestogen used in the contraceptive. The amount of both hormones should be considered in the choice of an oral contraceptive. Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral-contraceptive agents should be started on preparations containing less than 50 mcg of estrogen.

e. *Persistence of risk of vascular disease.* There are two studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for five or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. However, both studies were performed with oral-contraceptive formulations containing 50 micrograms or higher of estrogens.

2. *Estimates of Mortality from Contraceptive Use.* One study gathered data from a variety of sources which have estimated the mortality rate associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral-contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is less than that associated with childbirth. The observation of a possible increase in risk of mortality with age for oral-contraceptive users is based on data gathered in the 1970's–but not reported until 1983. However, current clinical practice involves the use of lower estrogen dose formulations combined with careful restriction of oral-contraceptive use to women who do not have the various risk factors listed in this labeling. Because of these changes in practice and, also, because of some limited new data which suggest that the risk of cardiovascular disease with the use of oral contraceptives may now be less than previously observed, the Fertility and Maternal Health Drugs Advisory Committee was asked to review the topic in 1989. The Committee concluded that although cardiovascular-disease risks may be increased with oral-contraceptive use after age 40 in healthy nonsmoking women (even with the newer low-dose formulations), there are greater potential health risks associated with pregnancy in older women and with the alternative surgical and medical procedures which may be necessary if such women do not have access to effective and acceptable means of contraception. Therefore, the Committee recommended that the benefits of oral-contraceptive use by healthy nonsmoking women over 40 may outweigh the possible risks. Of course, older women, as all women who take oral contraceptives, should take the lowest possible dose formulation that is effective.

3. *Carcinoma of the Reproductive Organs.* Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. The overwhelming evidence in the literature suggests that use of oral contraceptives is not associated with an increase in the risk of developing breast cancer, regardless of the age and parity of first use or with most of the marketed brands and doses. The Cancer and Steroid Hormone (CASH) study also showed no latent effect on the risk of breast cancer for at least a decade following long-term use. A few studies have shown a slightly increased relative risk of developing breast cancer, although the methodology of these studies, which included differences in examination of users and nonusers and differences in age at start of use, has been questioned. Some studies suggest that oral-contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. In spite of many studies of the relationship between oral-contraceptive use and breast and cervical cancers, a cause-and-effect relationship has not been established.

4. *Hepatic Neoplasia.* Benign hepatic adenomas are associated with oral-contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use. Rupture of rare, benign, hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral-contraceptive users. However, these cancers are extremely rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral-contraceptive users approaches less than one per million users.

5. *Ocular Lesions.* There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately.

6. *Oral-Contraceptive Use Before or During Early Pregnancy.* Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. Studies also do not suggest a teratogenic effect, particularly insofar as cardiac anomalies and limb-reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing oral-contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral-contraceptive use should be discontinued if pregnancy is confirmed.

7. *Gallbladder Disease.* Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral-contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral-contraceptive formulations containing lower hormonal doses of estrogens and progestogens.

8. *Carbohydrate and Lipid Metabolic Effects.* Oral contraceptives have been shown to cause glucose intolerance in a significant percentage of users. Oral contraceptives containing greater than 75 micrograms of estrogens cause hyperinsulinism, while lower doses of estrogen cause less glucose intolerance. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the nondiabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects, prediabetic and diabetic women should be carefully observed while taking oral contraceptives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As discussed earlier (see "Warnings" 1a. and 1d.), changes in serum triglycerides and lipoprotein levels have been reported in oral-contraceptive users.

9. *Elevated Blood Pressure.* An increase in blood pressure has been reported in women taking oral contraceptives and this increase is more likely in older oral-contraceptive users and with continued use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing quantities of progestogens. Women with a history of hypertension or hypertension-related diseases, or renal disease should be encouraged to use another method of contraception. If women with hypertension elect to use oral contraceptives, they should be monitored closely, and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension among ever-and never-users.

10. *Headache.* The onset or exacerbation of migraine or development of headache with a new pattern that is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause.

11. *Bleeding Irregularities.* Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. The type and dose of progestogen may be important. Nonhormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding, as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent.

Precautions

1. PHYSICAL EXAMINATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed, persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. (See "Warnings" 1d.) 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMOTIONAL DISORDERS. Patients becoming significantly depressed while taking oral contraceptives should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug related. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact-lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine-and liver-function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. b. Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral-contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINOGENESIS. See "Warnings" section. 10. PREGNANCY. Pregnancy Category X. See "Contraindications" and "Warnings" sections. 11. NURSING MOTHERS. Small amounts of oral-contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child.

Information for the Patient

See Patient Labeling.

Adverse Reactions

An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see "Warnings" section): thrombophlebitis, arterial thromboembolism, pulmonary embolism, myocardial infarction, cerebral hemorrhage, cerebral thrombosis, hypertension, gallbladder disease, hepatic adenomas or benign liver tumors.

There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: mesenteric thrombosis, retinal thrombosis.

The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug related: nausea; vomiting; gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; amenorrhea; temporary infertility after discontinuation of treatment; edema; melasma which may persist; breast changes: tenderness, enlargement, secretion; change in weight (increase or decrease); change in cervical erosion and secretion; diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.

The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: congenital anomalies, premenstrual syndrome, cataracts, optic neuritis, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, cerebral-vascular disease with mitral valve prolapse, lupus-like syndromes, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, impaired renal function, hemolytic uremic syndrome, Budd-Chiari syndrome, acne, changes in libido, colitis, sickle-cell disease.

Overdosage

Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Noncontraceptive Health Benefits

The following noncontraceptive health benefits related to the use of oral contraceptives are supported by epidemiological studies which largely utilized oral-contraceptive formulations containing doses exceeding 0.035 mg of ethinyl estradiol or 0.05 mg of mestranol.

Effects on menses: increased menstrual cycle regularity, decreased blood loss and decreased incidence of iron-deficiency anemia, decreased incidence of dysmenorrhea.

Effects related to inhibition of ovulation: decreased incidence of functional ovarian cysts, decreased incidence of ectopic pregnancies.

Effects from long-term use: decreased incidence of fibroadenomas and fibrocystic disease of the breast, decreased incidence of acute pelvic inflammatory disease, decreased incidence of endometrial cancer, decreased incidence of ovarian cancer.

Dosage and Administration

To achieve maximum contraceptive effectiveness, TRI-LEVLEN® tablets (Levonorgestrel and Ethinyl Estradiol Tablets—Triphasic Regimen) must be taken exactly as directed and at intervals not exceeding 24 hours.

For full details on dosage and administration see prescribing information in package insert. 60627-C 5/90

Gestational age in relation to marine *n*-3 fatty acids in maternal erythrocytes: A study of women in the Faroe Islands and Denmark

Sjúrður F. Olsen, MD, MSc,[a] Harald S. Hansen, Dr.Scient.,[b] Steffen Sommer, MD,[c] Benny Jensen, Lic.Tecn.,[b] Thorkild I.A. Sørensen, Dr.Med.Sci.,[d] Niels J. Secher, MD,[c] and Petur Zachariassen, Cand.Scient.[a]

Tórshavn, Faroe Islands, and Aarhus and Copenhagen, Denmark

Gestation is longer in Faroese than Danish women, possibly because of the high intake of marine long-chain *n*-3 fatty acids that down regulates formation of prostaglandins from arachidonic acid. Polyunsaturated fatty acids were quantified in erythrocytes obtained within 2 days of delivery from randomly selected groups of 62 Faroese and 37 Danish women with an assessable gestational age. Average ratio of long-chain *n*-3 fatty acids to arachidonic acid [(3/6) ratio] was 0.73 (SD = 0.11) in Faroese women and 0.61 (SD = 0.12) in Danish women ($p < 0.0001$), corresponding to the higher intake of marine *n*-3 fatty acids in the Faroes. A 20% increase in the (3/6) ratio was associated with an increase in pregnancy duration of 5.7 days in Danish women (95% confidence interval, 1.4 to 10.1 days; $p = 0.02$) and 0.7 days in Faroese women (95% confidence interval, −2.0 to 3.3; $p = 0.6$). The hypothesized exposure-effect relationship may be weaker or absent at the higher level of exposure seen in the Faroese group. (AM J OBSTET GYNECOL 1991;164:1203-9.)

Key words: *n*-3 fatty acids, erythrocytes, gestational age, birth weight, diet

Preterm delivery is one of the most important single risk indicators of perinatal death and neonatal morbidity.[1, 2] The majority of preterm deliveries in industrialized populations remains unexplained.[3]

The Faroe Islands are located in the North Atlantic Ocean between Norway and Iceland, and the population of 47,000 has, accordingly, a substantially higher consumption of marine foods than has the population of Denmark.[4] This, combined with the findings in the Faroe Islands of increased birth weights,[5] pregnancy durations, and rate of induced deliveries,[6] together with a suggestive case history,[7] made us hypothesize that a high maternal intake of marine fat, rich in long-chain *n*-3 fatty acids, increases birth weight by prolonging duration of pregnancy.[6] The hypothesis is biologically plausible, because the dienoic prostaglandins $F_{2\alpha}$ and E_2 are promoters of parturition[8] and their formation from arachidonic acid may be down regulated by a high intake of long-chain *n*-3 fatty acids.[6, 9]

Fatty acids of the *n*-3 series cannot be synthesized de novo in the mammalian organism.[10] The amount of long-chain *n*-3 fatty acids consumed is a determinant of their level in erythrocyte phospholipids,[11-13] making it possible to rank individuals according to their intake of long-chain *n*-3 fatty acids on the basis of blood samples. Compared with questionnaire-based dietary methods, this biochemical proxy for the intake has the great advantage of being independent of the individual's memory. However, its use in epidemiologic research is hampered by the laboriousness related to the biochemical analysis and the preparation of samples before storage.

This study was undertaken to explore whether there is indeed a difference in the long-chain *n*-3 fatty acids in maternal erythrocytes in Faroese and Danish women and whether a correlation exists between long-chain *n*-3 fatty acids and pregnancy duration in one or both of these populations.

Populations and methods

Populations. The study took place at Landssjúkrahúsid, the main hospital in the Faroe Islands, and at Aarhus University Hospital in Denmark (approximately 550 and 3600 deliveries per year, respectively). Both hospitals have well-defined catchment areas, and neither of them refers women to other hospitals for delivery (except in certain cases in the Faroes, e.g., rhesus immunization, when the woman may be referred to a specialized ward in Denmark). In both areas >99% of deliveries take place in hospitals or maternity units.

Data collection. Mothers of live-born singleton infants from the catchment areas were eligible for the study provided they had no gross pathologic conditions. The Faroese group included all eligible deliveries at the Landssjúkrahúsid during a 5-week period from October to November 1985. The Danish group included all eligible deliveries at Aarhus Kommunehospital during six randomly chosen days (24 hours) in a 5-week period from November to December 1985. Within 5 to 48 hours of delivery a peripheral venous sample was drawn. Information was obtained by a standardized interview of the mother and from hospital records, birth certificates, and records of antenatal visits. Gestational age was assessed according to an elaborate procedure designed by Hall et al.[14]; it is based primarily on menstrual data and also provides a decision scheme for stratifying deliveries according to certainty of the gestational age estimate. Assessment of gestational age was done independently of the results of biochemical analyses.

The study groups. Of the 52 Danish and 83 Faroese deliveries that took place during the data collection periods, two in each group were not eligible because of preeclampsia, rhesus immunization, insulin-dependent diabetes mellitus, or twin pregnancy. One Danish and two Faroese women refused to give blood samples, and samples from three Danish and seven Faroese women were lost. Nine Danish and 10 Faroese women had either uncertain estimate of gestational age or elective delivery; since the outcome of interest in the present study relates to the timing of spontaneous onset of delivery, these women were regarded as not eligible for analysis (however, elective postterm deliveries were included). A total of 37 Danish and 62 Faroese deliveries were included in the analysis (90% and 87% of the deliveries eligible for analysis, respectively).

Statistics. When groups were compared, either Student's t test or χ^2 test was applied. When associations between fatty acids and gestational age were investigated, linear regression was applied. Factors considered determinants of gestational age[8] that might also possibly be associated with intake of n-3 fatty acids in the study populations were treated as potential confounders: maternal prepregnant weight, height, age, parity, marital status, smoking, and employment during pregnancy (proxy for work load) (the last four factors were dichotomous). The potential joint confounding effect of these variables on the association between gestational age and the (3/6) ratio was controlled for by adding them as a group into a multiple regression model. When the term *significant* is being used, it refers to a p value of <0.05.

Biochemical material and methods

Biochemical analyses. The blood sample was immediately put on ice, and within an hour erythrocytes were isolated as described by Dodge and Phillips,[15] rinsed three times, and finally stored in 1.5 ml saline solution with 0.005% (wt/vol) butylated hydroxytoluene at −20° C. The thawed erythrocytes were resuspended and a 1 ml aliquot was taken for analysis. Then 2 ml of ice-cold methanol with 0.01% butylated hydroxytoluene was added, and the lipid extraction was carried out as described by Dodge and Phillips.[15] Methyl ester preparation and gas chromatography were performed essentially as described by Hansen and Jensen.[16] The fatty acid methyl esters in total lipids were tentatively identified by comparison of retention times with those of authentic standards (Nu-Chek Prep, Inc., Elysian, Minn.) or by calculating equivalent chain lengths of homologous series of fatty acid methyl esters.[17] For retention times where critical pairs of methyl esters were suspected, a supplementary gas chromatographic analysis was carried out on a limited number of samples. For this purpose a nonpolar column was used (30% SE-30 on 80/100 mesh Gas Chrom P, Applied Science, State College, Penn.). On the 10% SP-2330 column used for routine gas chromatography, the fatty acids 22:0 and 20:4 did not always separate, i.e., 22:0 was sometimes seen as a shoulder on the 20:4 peak. Thus these two fatty acids were calculated as one peak, referred to hereafter as 20:4 (n-6). In extracts of total lipids, 22:0 amounted to approximately 14% of the 20:4 (n-6) peak. Peak areas corresponding to butylated hydroxytoluene, to methyl heptadecanoate, and to dimethylacetals of the aldehydes 16:0, 18:0, and 18:1, or with retention times beyond 22:6, were excluded from the calculation of the peak area percentages.

Biochemical variables used in the statistical analyses. From the peak area percentages of three long-chain n-3 fatty acids, eicosapentaenoic acid, 20:5 (n-3); docosapentaenoic acid, 22:5 (n-3); and docosahexaenoic acid, 22:6 (n-3); and of arachidonic acid, 20:4 (n-6), the ratio of the sum of the three long-chain n-3 fatty acids to arachidonic acid was calculated [the (3/6) ratio]. Logarithmic transformation of this ratio, which was skewed to the right, tended to fit the linear model better.

Stability and reproducibility. No significant changes in polyunsaturated fatty acids were seen during storage for 12 months at −20° C; five assessments ($n = 4$) were made during the period, and all samples were taken at the same time from one person. The blood samples included in the study were stored for a maximum period of five months. Coefficients of variation for the long-chain fatty acids ranged from 5% to 7%.

Prepartum versus postpartum sampling. Blood samples taken from 16 pregnant Danish women at the thirty-seventh week of gestation and again within 1 day of delivery showed no significant differences in any of the four fatty acids (paired t tests), and the differences

were not correlated with the duration from first to second sampling, which ranged from 3 to 34 days, with an average of 17 days. The difference between prepartum and postpartum levels of the (3/6) ratio was 0.0022 (95% confidence interval, −0.032 to 0.036; $p = 0.9$).

Results

Eicosapentaenoic acid and docosahexaenoic acid occurred in significantly higher percentages in the Faroese group, whereas docosapentaenoic acid and arachidonic acid showed similar values in the two groups (Table I). The sum of long-chain *n*-3 fatty acids and the ratio of this sum to arachidonic acid [the (3/6) ratio] were significantly greater in the Faroese than in the Danish group ($p < 0.0001$). Average gestational age was 2.0 days longer and birth weight was 140 gm higher in the Faroese group than in the Danish group, but the differences were not significant (Table II). There were significantly more primiparous women in the Danish group, but maternal age, prepregnant weight, and height and the proportions of women who were single, who smoked, or who were employed during pregnancy were similar for both groups (Table II). Including women with uncertain lengths of gestation and with elective deliveries did not alter these conclusions.

The relation between gestational age and the (3/6) ratio is shown in Fig. 1. In the simple regression of gestational age on the log-transformed (3/6) ratio, a positive and borderline significant association was seen in the separate analysis of Danish women but not in that of Faroese women (Table III, models 1 and 3).

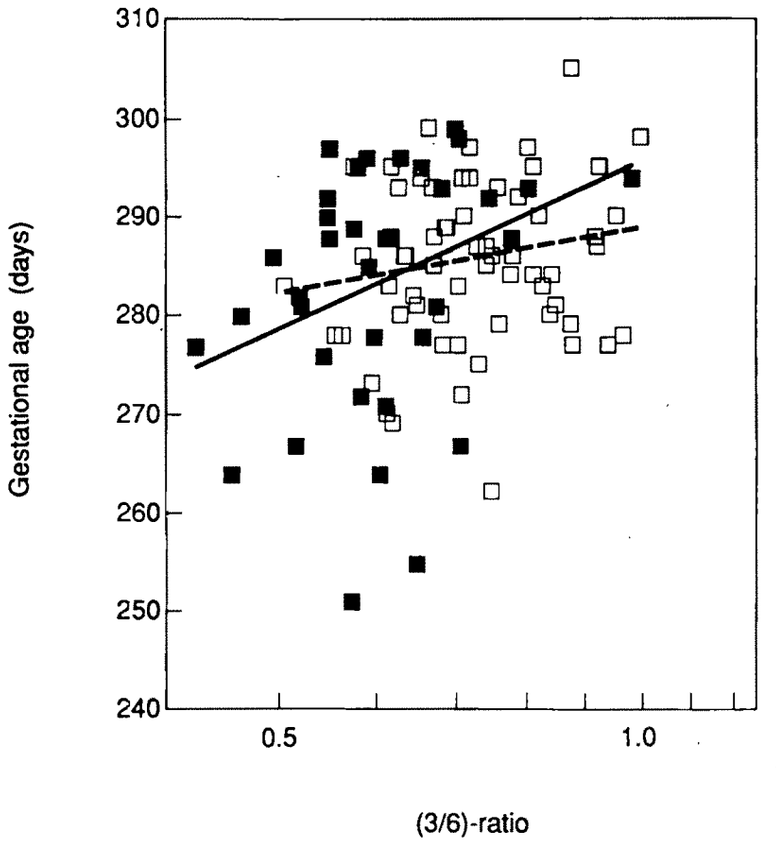

Fig. 1. Gestational age and (3/6) ratio. Danish and Faroese deliveries are indicated by *black* and *white squares,* respectively. Fitted lines from regression analyses of Danish and Faroese groups are given as *solid line* and *dashed line,* respectively. The x axis is logarithmically transformed. The equation of the Danish fitted line is: Gestational age = 55.1 × $\log_{10}$(3/6 ratio) + 295. The equation of the Faroese fitted line is: Gestational age = 18.8 × $\log_{10}$(3/6 ratio) + 288.

Controlling for potential confounders strengthened the association seen in Danish women (model 2 vs 1) and weakened that seen in Faroese women (model 4 vs 3).

To control for site of origin in the analysis of the combined groups, the variable *Residence* was used. Neither in the model with potential confounders nor in that without was there significant interaction (p = 0.07 and 0.2, respectively) between the (3/6) ratio and *Residence,* as expressed by the product term: (3/6) Ratio × Residence (Table III, models 5 and 6). In a model with no interaction assumed, only minor changes were seen in the regression coefficient of the (3/6) ratio when potential confounders, including the *Residence* variable, were eliminated from the model (Table III, models 7 to 9).

The associations between gestational age and the sum of the long-chain *n*-3 fatty acids were generally weaker than the associations between gestational age and the (3/6) ratio, but similar trends were seen. Thus the correlation coefficient between gestational age and the log-transformed sum was 0.22 (p = 0.2) in the Danish group, 0.07 (p = 0.6) in the Faroese group, and 0.17 (p = 0.1) in the combined groups, whereas the corresponding correlation coefficients between gestational age and the log-transformed (3/6) ratio were 0.33 (p = 0.05), 0.15 (p = 0.2), and 0.25 (p = 0.01), respectively.

Comment

The hypothesis of this study, i.e., that dietary long-chain *n*-3 fatty acids prolong gestation, is based on the contention that long-chain *n*-3 fatty acids inhibit the formation of the dienoic prostaglandins from their obligate precursor, arachidonic acid.[6, 9, 10] Thus the ratio of long-chain *n*-3 fatty acids to arachidonic acid [the (3/6) ratio] seems to be the most reasonable single biochemical measure of exposure. The average (3/6) ratio of Faroese women was significantly greater than that of Danish women; this was to be expected[11-13] because the intake of marine fat is substantially higher in the Faroes.[4]

A positive association was seen between pregnancy

Residence (Faroes = 0; Denmark = 1)	0.685 ± 2.32	0.8			
Model 9					
(3/6) Ratio alone	31.9 ± 12.4	0.01	1	97	0.252

*The seven potential confounders are listed in the Statistics section. The regression coefficient of the (3/6) ratio is given in days per unit change of the $\log_{10}$-transformed ratio, with one unit equaling a 10 times increase in the ratio; multiplying the regression coefficient by $\log_{10}(1.5)$ or by $\log_{10}(1.2)$ changes the unit of the regression coefficient to days per 50% increase or per 20% increase, respectively, in the ratio. *df*, Degrees of freedom. Further details about the analyses are available from the authors.

duration and the (3/6) ratio in the Danish group, whereas no association could be detected in the Faroese group. Thus, after allowances were made for seven potential confounders, a 20% increase in the (3/6) ratio was estimated to be associated with an increase in pregnancy duration of 5.7 days in Danish women (95% confidence interval, 1.4 to 10.1 days; $p = 0.02$) and 0.7 days in Faroese women (95% confidence interval, −2.0 to 3.3; $p = 0.6$) (Table III, models 2 and 4). In theory, three possible explanations may be considered. First, the true relationship is being reflected in the association seen in the Danish group, and the absence of association in the Faroese group is due to statistical error (type II) or to some source of bias not controlled for, such as saturation of phospholipid fatty acid pools in the Faroese women.[18] Second, there is no causal relationship between maternal *n*-3 fatty acid intake and pregnancy duration, and the association seen in the Danish group is due to statistical error (type I) or bias. Third, the results from both groups represent the truth, i.e., the associations differ in the two populations; indeed this possibility was foreseen as a subordinate, a priori hypothesis because, even if the main hypothesis of an effect of *n*-3 fatty acids on gestational age were true, the exposure distribution of one of the two populations could be below or above the working range of the exposure-effect relationship. However, the difference between the estimates of association (measured by the term of interaction in the combined analysis) did not reach the conventional level of statistical significance. Exploring whether the associations truly do differ in the two populations and refining the model by, for

instance, searching for threshold effects would require a new study with a larger sample size.

According to our previous studies that were based on birth certificates from much larger numbers of women than in the present study, average birth weight of live-born babies in the Faroes was highest among 33 geographically defined populations.[5] Average birth weight and gestational age of live-born singleton infants of primiparous women were 194 gm higher and 3.6 days longer, respectively, in the Faroes than in Denmark.[6] Women delivered after 41 completed weeks of gestation were 1.9 times more frequent in the Faroes and those delivered before 37 completed weeks were 1.8 times more frequent in Denmark; these differences could not be attributed to a difference in induction practice because the proportion of induced deliveries was highest in the Faroes.[6] Information from birth certificates from the two populations is comparable, as the forms in use are identical and computerized at the same office. Practically all doctors and midwives in the Faroes have been trained in Denmark, ensuring similar obstetric procedures and terminology.

The average (3/6) ratio was about 20% higher in the Faroese than in the Danish group. As interaction between the *Residence* variable and the (3/6) ratio was nonsignificant, the model assuming no interaction may be used to estimate the "average effect"[19] in the two populations. In this model (Table III, model 7) a 20% increase in the (3/6) ratio was accompanied by a 2.8-day increase in pregnancy duration (95% confidence interval, 0.5 to 5.2 days; $p = 0.02$). Although the wide confidence interval around the estimate should be kept in mind, it is compatible with the difference of 3.6 days observed between the two populations in our previous study[6] referred to above.

To our knowledge, only one controlled trial has been published where *n*-3 fatty acids were given to pregnant women. During 1938 to 1939 in London, >5000 women were alternately allocated to receive either no supplement or a supplement with vitamins, minerals, and halibut liver oil.[20] The trial, which has recently been reviewed,[21] was of comparatively high standard.[21] A significantly smaller proportion of pregnancies with short durations was seen in the supplemented group. It is not possible to tell which of the components of the treatment caused the effect, but it is striking that this effect has not been demonstrated convincingly in later controlled trials undertaken with vitamins and minerals given in the same amounts as in the London trial.[21]

Grundy et al.[22] found that women of Asian origin had shorter average pregnancy duration and fewer postterm and induced deliveries than Caucasian women, although they were living in the same area of London, were delivered at the same hospital, had similar distributions as to parity and social class, and had a lower proportion of smokers. No information was provided on the nutritional habits of this Asian group, but McKeigue et al.[23] found a high proportion of vegetarians and a low fish intake in an Asian group that was defined similarly as to country of origin and where they were living in London (mainly Hindus); this was supported by the finding of lower levels of *n*-3 fatty acids and higher levels of *n*-6 fatty acids in plasma cholesterol esters of men from this Asian group than in those of Caucasian men in the United Kingdom. Although alternative explanations cannot be excluded, the finding of shorter gestations in Asian women is apparently in agreement with our hypothesis.

A greater proportion of early deliveries was found in rats supplemented with arachis oil, which is high in *n*-6 fatty acids, than in rats supplemented with fish oil, which is high in *n*-3 fatty acids; this finding is also compatible with the basic idea that a high ratio of *n*-3 to *n*-6 fatty acids in the diet postpones delivery.[24]

In a review on nutrition and pregnancy duration, Kristal and Rush[25] stated that there is little to suggest much of an association between diet and duration of gestation among adequately nourished women in developed countries. The results from our study indicate that some previously unrecognized aspects of the diet may be of significance. However, further studies are needed to explore whether the statistical association seen in the Danish group truly does reflect a causal relationship between intake of marine *n*-3 fatty acids and gestational age. A trial assessing the effect of marine *n*-3 fatty acids on pregnancy duration seems justified. It should preferably be done on a multicenter basis, permitting assessment of the potential preventive effects on premature delivery and on other adverse pregnancy outcomes.[26]

We thank Lotte Klamer and Jytte Christiansen for technical assistance. We acknowledge advice from the National Perinatal Epidemiology Unit, Oxford, England, in the planning of the study.

Recurrent failure of in vitro fertilization: Role of the hemizona assay in the sequential diagnosis of specific sperm-oocyte defects

Sergio Oehninger, MD,[a] Anibal A. Acosta, MD,[a] Lucinda L. Veeck, MLT,[a] Robert Brzyski, MD, PhD,[a] Thinus F. Kruger, MD,[b] Suheil J. Muasher, MD,[a] and Gary D. Hodgen, PhD[a]

Norfolk, Virginia, and Tygerberg, Republic of South Africa

The results of predictive fertilization bioassays (hemizona assay, hamster ova–human sperm penetration assay), in vitro fertilization treatment, fertile donor cross-match tests with either sperm or oocytes, and oocyte micromanipulation for assisted fertilization were used to establish a pathophysiologic diagnosis in cases of recurrent failed fertilization in vitro. Disorders of sperm function manifested at the level of zona binding, zona penetration, oolemma fusion, and pronuclear decondensation as well as oocyte anomalies were considered to represent the specific gamete defects that led to abnormal sperm-oocyte interactions (i.e., failed fertilization). Our findings show that the sequential application of bioassays can elucidate specific sperm or oocyte defects that characterize functional abnormalities among sperm populations. (AM J OBSTET GYNECOL 1991;164:1210-5.)

Key words: Failed fertilization, sperm function disorders

In the Norfolk in vitro fertilization (IVF) and embryo transfer program, failure of fertilization of mature, preovulatory oocytes has been observed in 8.9% of patients and 5.7% of cycles.[1] Certain aberrations of the fertilization process have been recognized including polyspermia in 9.0% of preovulatory oocytes and delayed fertilization in 1.8% of cycles.[1,2] Whereas these abnormalities may point to inadequately timed oocyte insemination or inappropriate in vitro culture conditions, it is more likely that gamete defects are contributory. Whatever the underlying cause(s), such factors combine to have a significant negative impact on the overall success of IVF treatment.

An elusive goal remains in the search for a test that will accurately predict IVF outcome. In a previous article,[3] we reported that sperm morphology evaluated by strict criteria is a useful predictor of IVF results. Motility indexes are not indicators unless progressive motility is <15% or when <1.5 million motile sperm are obtained after swim-up separation.[4] Thus, tests designed to evaluate functional sperm (and oocyte) normalcy relative to IVF outcome become relevant so that patients can be counseled accordingly. In this regard, the homologous hemizona assay,[5] a zona penetration assay,[6] and the heterologous zona-free hamster ova–human sperm penetration assay[7] constitute differential bioassays that evaluate tight sperm-oocyte binding, zona penetration, oocyte fusion, and decondensation in sequence.

Here, we have studied IVF treatment failure in four couples to establish a pathophysiologic diagnosis for specific functional defects of sperm-oocyte interactions during the fertilization process and to develop a serial diagnostic scheme for cases of recurrent fertilization failure in vitro. It is hoped that the information gained can be useful in the selection of optimal therapy, such as modification of standard IVF methods or micromanipulation of oocytes for assisted fertilization.[8-12]

Material and methods

Patients, semen analysis, and endocrine profile. Four couples participating in the Norfolk IVF program during seven treatment cycles constituted the study group. Semen samples (at least two collections) were evaluated for sperm concentration, percentage of motility, velocity, and linearity (Cellsoft Semen Analyzer, Cryo Resources, Ltd., New York), percentage of normal forms (strict criteria), bacteriology, and immunology (direct immunobead test), according to published methods.[1,3,4,9] Serum endocrine evaluations were performed as described.[4] The male partners in all couples

had normal physical examination results, negative results of bacteriologic and immunologic evaluations, and normal serum endocrine profile results.

In vitro fertilization and embryo transfer procedures. Ovarian stimulation protocols, semen processing for IVF, oocyte insemination, and embryo culture and transfer were performed according to established guidelines.[1, 2] Because of the abnormal sperm parameters observed in their original semen samples and a history of failed fertilization during one or more IVF treatment cycles, each oocyte was inseminated with a 10-fold higher sperm per milliliter concentration (0.5 to 2.0 $\times$ 10^6 motile sperm after swim-up separation).[9] In all cases, the total number of motile spermatozoa recovered after swim-up was $>1.5 \times 10^6$. No attempts were made to remove the cumulus oophorus either mechanically or enzymatically in any of the cases.

Cross-match test in IVF. When patients agreed and after their written consent was obtained, cross-match tests were performed as follows: (1) the wife's oocytes (metaphase II or immature, in vitro–matured metaphase II) were inseminated with frozen-thawed donor semen (fertile controls) at 500,000 motile sperm per milliliter per oocyte, and (2) donor oocytes (prophase I matured to metaphase II in vitro) were inseminated with the husband's semen at the same concentration. If fertilization occurred, as judged by normal pronuclear formation, further development was not allowed, or culture was continued until transfer, as previously decided by the couple.

Sequential specific sperm defect analysis

Tight binding and penetration of the zona pellucida. We have used the hemizona assay to test for a defective sperm-zona interaction.[5, 13-15] Human oocytes harvested from surgically removed ovaries and stored in salt solution were used in the study.[5, 13] In each study, one hemizona was coincubated with the patient's swim-up processed semen, whereas the matching hemizona was incubated with donor's sperm (fertile control). Tight binding was assessed after 4 hours of gametes coincubation.[5]

Acrosome reaction and oolemma fusion. By use of the hamster test or sperm penetration assay, we evaluated the ability of the human sperm to undergo the acrosome reaction and fuse with the denuded hamster oocyte membrane.[7, 8] Biggers, Whitten, and Whittingham medium was used for incubation supplemented with 3% bovine serum albumin in a 6-hour incubation protocol.[8] All control semen samples (fertile donors) penetrated >20% of eggs.

Sperm decondensation and pronuclei formation. Oocyte micromanipulative procedures for assisted fertilization were accomplished following the methods of Lanzendorf et al.[16] (microinjection of a single spermatozoon into the cytoplasm of the oocyte) or Cohen et al.[17] (partial zona dissection) after Institutional Review Board approval and written consent from the patients were obtained.

Results

Couple 1. This couple had primary infertility of 10 years' duration. The wife and husband were 33 and 34 years old, respectively. The wife's workup showed stage II endometriosis (revised American Fertility Society classification).[18] Semen analysis revealed 52 million sperm per milliliter, motility 37%, velocity 33 μm/sec, linearity 5.2, 49 million motile sperm per ejaculate, 0% normal forms, and an 11% morphology index (poor prognosis pattern, defined as <4% normal forms and morphology index <30%),[3] an hemizona assay index of 0 (number of patient's tightly bound sperm per control $\times$ 100, normal = 100),[5] and sperm penetration assay (test vs control) 0% vs 32%. In the two IVF attempts, no fertilization occurred among four mature (metaphase II) oocytes. The couple chose not to do a cross-match test and not to have oocyte microsurgical procedures performed (Tables I and II).

Couple 2. This couple had primary infertility of 5 years' duration. The wife and husband were 38 and 37 years old, respectively. The wife's workup revealed a tubal factor (failed bilateral fimbrioplasty). The husband's semen analysis showed sperm concentration 59 million per milliliter, motility 40%, velocity 26 μm/sec, linearity 7.0, 104 million motile sperm per ejaculate, 6% normal forms, 42% morphology index (good prognosis pattern),[3] hemizona assay index of 75, and sperm penetration assay 27% vs 28% (Tables I and II).

Four IVF attempts at different institutions resulted in no fertilization of multiple eggs. Two IVF attempts were made in Norfolk. In the first attempt, 11 preovulatory (metaphase II) oocytes were recovered. Nine metaphase II and three immature (prophase I) oocytes were obtained in the second IVF attempt.

In the first IVF attempt, no fertilization occurred in seven metaphase II oocytes; one of four microinjected metaphase II eggs fertilized and was transferred at the two-cell stage after incubation for 40 hours. In the second IVF cycle, no fertilization was observed among four metaphase II oocytes. One of three microinjected oocytes fertilized and was transferred at the pronuclear stage. Neither of the two preovulatory, metaphase II eggs subjected to partial zona dissection fertilized. Two immature (prophase I) eggs matured in vitro were inseminated with donor sperm; both fertilized but were not transferred. In addition, one donor egg failed to fertilize after insemination with husband's sperm (Table II).

Couple 3. This couple had infertility of 3 years' du-

ration. The wife and husband were 29 and 32 years old, respectively. The wife's workup was normal. Semen analysis results were sperm concentration 143 million per milliliter, motility 71%, velocity 36.4 μm/sec, linearity 6.2, 369 million motile sperm per ejaculate, 4% normal forms, 32% morphology index (good prognosis pattern),[3] hemizona assay index of 65 (Tables I and II), and sperm penetration assay 0% vs 100% (Tables I and II).

Three IVF attempts in another treatment program resulted in the collection of multiple eggs with no fertilization. Two IVF attempts were made in Norfolk. In the first IVF cycle, no fertilization was observed among 11 metaphase II oocytes. Four other metaphase II eggs were microinjected; all displayed normal pronuclear formation and were transferred at the two-cell stage at 40 hours.

In the second IVF cycle, no fertilization occurred with seven metaphase II oocytes. Three other preovulatory metaphase II eggs were inseminated with donor semen. All three were fertilized and transferred at the four-cell stage; two metaphase II oocytes were microsurgically manipulated by partial zona dissection, but none fertilized. Two of six prophase I eggs that were microinjected at the metaphase II stage fertilized and were cryopreserved at the pronuclear stage with 1,2-propanediol and remain in storage. In addition, none of two donor eggs was fertilized by the husband's sperm, although numerous sperm were observed at the zona (Table II).

Couple 4. This couple had primary infertility of 3 years' duration. The wife and husband were 31 and 30 years old, respectively. The wife's workup revealed severe endometriosis (revised American Fertility Society classification, stage IV). The semen analysis showed a sperm concentration of 31 million per milliliter, motility 48%, velocity 40 μm/sec, linearity 6.0, 83 million motile sperm per ejaculate, 6% normal forms, morphology index 30% (good prognosis pattern), hemizona assay index 108, and sperm penetration assay 20% vs 25% (Tables I and II).

Three attempts at different centers resulted in no fertilization of multiple oocytes. In one attempt, delayed fertilization of two metaphase II oocytes occurred with subsequent embryo transfer but no pregnancy. One IVF attempt was carried out in Norfolk with seven metaphase II oocytes retrieved. No fertilization occurred in six oocytes; delayed fertilization was observed in one egg.

Comment

Despite the limited data available, this study shows the feasibility of establishing a pathophysiologic diagnosis in cases of recurrent failed IVF treatment by sequential clinical and laboratory analysis. Our findings indicate that application of the hemizona assay, sperm

penetration assay, standard IVF, donor gamete crossmatching and assisted fertilization techniques, permit identification of specific sperm-oocyte dysfunctions. The order of progression may be important because those sperm defects that prevent tight binding of sperm to the zona pellucida or its penetration will negate subsequent functional tests. Accordingly, the hemizona assay should be applied first. Men whose specimens show adequate tight binding and penetration under hemizona assay conditions can be examined next for acrosome reaction, oolemma fusion, decondensation, and pronuclear formation in sequence.

Couple 1 represents a severe male factor case with a high percentage of abnormal sperm forms (mainly morphologic head defects; poor prognosis pattern).[3, 9] Morphology alone predicted a poor IVF outcome; despite increasing sperm insemination concentration by 10-fold, fertilization did not occur.[9] In addition, the hemizona assay, with an index of 0, clearly identified this patient at high risk of failed fertilization.[14] Because we have observed previously a good correlation between the incidence of abnormal sperm forms and poor binding capacities in the hemizona assay, this case represents a lack of fertilization because of a functional defect disorder in this first step.[14, 19] Because of an abnormality in sperm-zona binding, micromanipulative procedures that assist fertilization by bypassing the zona deserve consideration as a therapeutic approach.[11, 16, 17] This patient also showed negative sperm penetration assay results, signaling multiple sperm defects. If poor sperm penetration assay results are a result of abnormalities in sperm-egg fusion, then microinjection of a spermatozoon into the oocyte cytoplasm might be beneficial. However, if poor sperm penetration assay results are because of an abnormal sperm decondensation (sperm-oocyte disorder) then the remedy may be to consider donor gametes.

In couple 2, female diagnosis was mechanical (tubal) infertility; male diagnosis was asthenoteratospermia. Unlike the previous case, sperm binding to the zona was satisfactory; in addition, sperm performance in the sperm penetration assay was adequate, implying normal capacitation, acrosome reaction, fusogenic ability, and decondensation into zona-free eggs. Also pronuclei formation occurred after microinjection. However, neither the wife's nor the donor's oocytes fertilized in vitro. That donor semen fertilized some of the wife's eggs is evidence of adequate oocyte quality. These results point to a defect in the ability of the sperm to penetrate the zona pellucida as the subjacent cause of failed fertilization. A zona penetration assay[6] and electron microscopic evaluation[15] of the unfertilized oocytes may further clarify this diagnosis. The mechanisms of sperm penetration of the zona are not completely understood but probably require receptor-ligand events, adequate motility patterns, and enzymatic mechanisms. Subtle disorders in any of these mechanisms may contribute to impaired zona penetration.

Considered alone, hemizona assay results for patient 2 produced a false-positive result, as did sperm penetration assay results. We have previously reported[7] that negative sperm penetration assay results may not reliably correlate with IVF outcome (high incidence of false-negative results); however, we have observed a positive correlation between a good sperm penetration assay performance and successful IVF. Also, the fact that in the second patient's transfer the preembryo was at the pronuclear stage suggests delayed or arrested development after oocyte microinjection. We have observed a lower cleavage rate in microinjected eggs as compared with the usual cleavage rate after IVF, perhaps implying a compromised developmental potential of some of these micromanipulated oocytes either because the sperm is inferior or the method is flawed.

Couple 3 had no identifiable female abnormalities; male clinical diagnosis was teratospermia. The morphology score was on the verge of poor with modest hemizona assay index. That no penetration was observed in the sperm penetration assay and no fertilization occurred in IVF with the wife's or donor's eggs suggest a severe male factor. The fact that the wife's oocytes were successfully fertilized by donor sperm confirms the absence of a female factor and supports the probability of adequate oocyte quality. Because microinjected sperm decondensed and formed pronuclei, we suggest that those sperm functions (or oocyte and sperm functions) were satisfactory, thus pointing to an abnormality at the level of sperm-egg fusion (spermatozoon-oolemma interactions). This opinion also fits with the finding that no fertilization occurred after an opening was mechanically created in the zona. Perhaps a sperm receptor defect or an abnormal acrosome reaction is the underlying cause.

The hemizona assay is an internally controlled, homologous bioassay with good predictive value for IVF results.[14, 19] Earlier, we reported positive and negative predictive values of 95% and 83%, respectively, in anticipating IVF outcome with the hemizona assay.[14] However, the findings in couples 2 and 3 represent false-positive results. According to current standards, an hemizona assay index value of ≥ 36 correlates positively with successful fertilization in IVF, although scores nearer 100 are more desirable.[14, 20] As we indicated, it is important to realize that other steps after the binding of sperm to the zona are necessary for fertilization and viable embryo development. Accordingly, such false-positive results are expected but have been infrequent in our experience. Because hemizona assay results are overall good predictors of IVF outcome,[14, 19] it may well be that sperm binding to the zona pellucida is one of

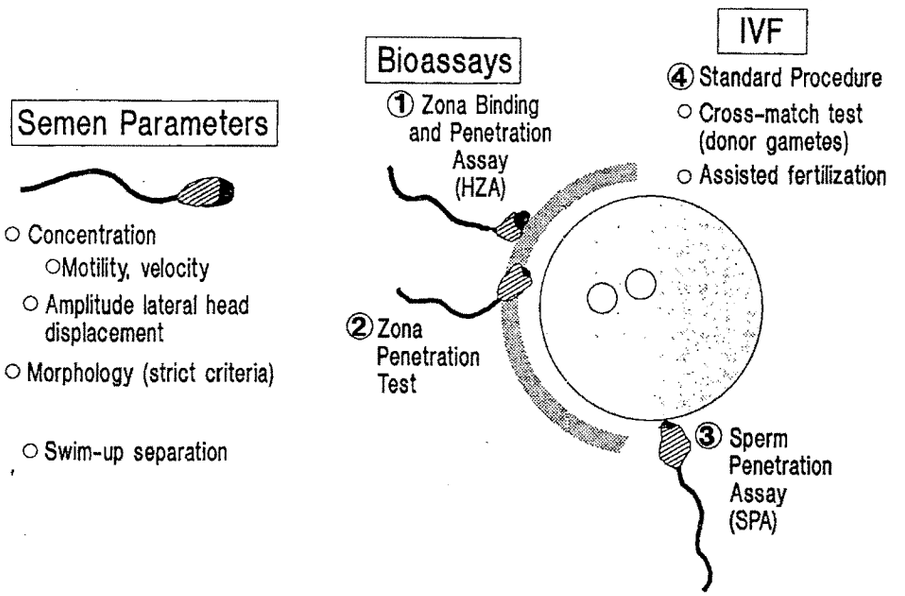

Fig. 1. Diagnostic scheme to establish a step-wise progressive diagnosis in cases of recurrent failed IVF.

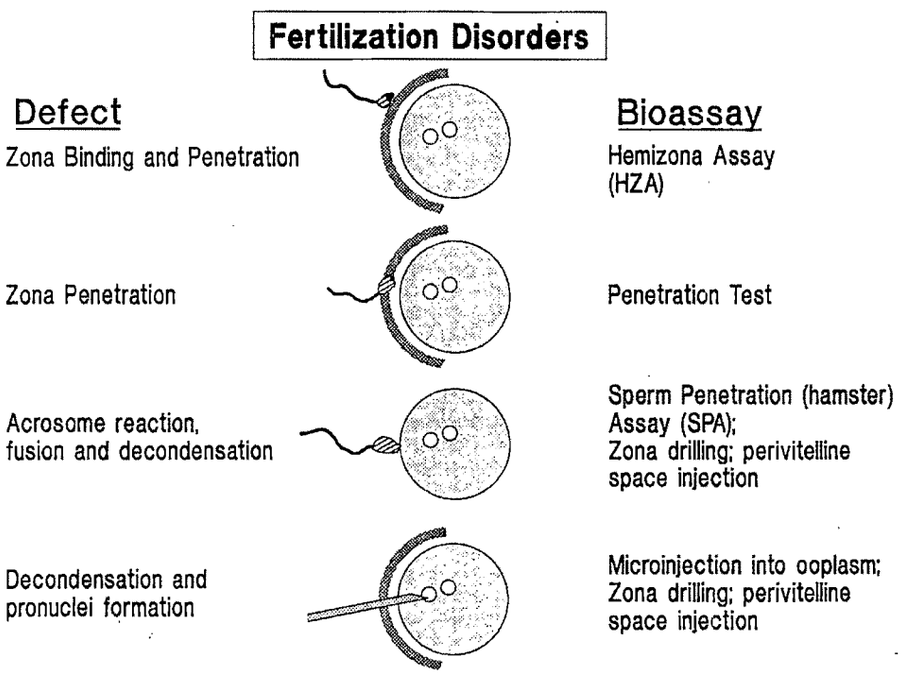

Fig. 2. Sequential analysis of specific sperm defects in cases of recurrent failed fertilization in vitro.

the more critical steps in achieving fertilization, and that fertilization failures that occur after zona-binding stages are less common or correlated to observations in zona binding.

Couple 4 represents an apparent case of poor oocyte quality. Overall, the semen sample was of acceptable quality except for teratospermia and within a good prognosis pattern. The results of the hemizona assay and sperm penetration assay were quite favorable. In addition, the husband's sperm successfully fertilized a donor egg (male cross-match test). Although the couple did not accept a female cross-match test (wife's eggs inseminated with donor sperm), we suggest that multiple failures and one delayed fertilization were a

result of oocyte dysfunction(s).[2] We have observed several oocyte defects in cases of failed and delayed fertilization.[1,2] Whether the poor oocyte quality is intrinsic or whether it is iatrogenic (stimulation-induced) remains to be investigated. Oocyte dysfunctions responsible for fertilization disorders might reside in the zona pellucida, oolemma, or ooplasm (sperm decondensation is estimated to be largely an oocyte function dependent on breakage of disulfide bonds of the condensed head by glutathione or glutathione-like substances).[21] In special circumstances, electron microscopic studies may help to determine the fate of the sperm cells whether in the zona, perivitelline space, or inside the oocyte.

The limited number of couples studied here must be acknowledged, but serves us well in showing that bioassays of fertilization potential, IVF treatment, gamete cross-match tests during IVF, and assisted fertilization techniques contribute sequentially to achieving full defects analysis on sperm-oocyte interactions. Thus, a diagnostic scheme for cases of recurrent fertilization failure can be applied as illustrated in Figs. 1 and 2. Although much more research and a larger patient series is needed to accomplish full diagnosis of gamete defects, ultimately a solid diagnosis remains the optimal course to development of effective male factor infertility treatment.

Umbilical vein administration of oxytocin for the management of retained placenta: Is it effective?

Maarten G.P. Huber, MD,[a] Hajo I.J. Wildschut, MD, PhD,[a, d] Kees Boer, MD, PhD,[a] Gunilla Kleiverda, MD,[b] and Frans J. Hoek, PhD[c]

Amsterdam, The Netherlands, and Bristol, United Kingdom

In a multicenter randomized controlled trial involving 220 women with retained placenta no beneficial effects could be established of intraumbilical vein administration of 10 IU of oxytocin in 20 ml of saline solution. A reduction was not gained in the rate of manual removal of the placenta and there was no decrease in the amount of blood loss. Oxytocin only induced a minor shortening of the median time interval from administration to the spontaneous expulsion of the placenta as compared with a placebo injection. Maternal serum α-fetoprotein levels before and after intraumbilical vein injection did not show evidence of fetomaternal transfusion. (Am J Obstet Gynecol 1991;164:1216-9.)

Key words: Retained placenta, labor third stage, randomized controlled trial, oxytocin, umbilical vein, α-fetoprotein, fetomaternal transfusion

After vaginal delivery, a retained placenta forms a substantial risk to maternal health.[1] Manual removal of the placenta is not without danger. Any other treatment that might reduce the need to perform this procedure is of interest. The intraumbilical injection of oxytocin to induce the spontaneous expulsion of the retained placenta was first published by Senatore[2] in 1953. In 1983, Golan et al.[3] published the method in this Journal. They injected 20 ml of saline solution that contained 10 IU of oxytocin in 10 parturients with retained placenta. Within minutes this resulted in the spontaneous expulsion of the placenta in all the women. This publication prompted us to carry out a randomized, double-blind, controlled study in women with retained placenta to evaluate the efficacy of this promising treatment.

Material and methods

Between Feb. 1, 1986, and Jan. 31, 1989, parturient women from eight participating hospitals were enrolled in the study. Inclusion criteria were similar to those formulated by Golan et al.[3]: retention of the placenta for 30 minutes or more after the vaginal delivery of a singleton infant of at least 28 weeks' gestation (196 days).

After informed consent was given, for each woman a box was taken in numeric order from a stock of identical white sealed boxes that bore a serial code, by which randomization occurred in three groups: an oxytocin-treated group (group 1), a placebo-treated group (group 2), and a group of nontreated control subjects (group 3). For this a blocking procedure[4] was used whereby the number of patients in each group was balanced in small blocks of a fixed size ($n = 6$). The boxes contained a questionnaire, an unmarked ampule, and instructions for its use. The code was held by M.H. and was broken after completion of the trial.

In the questionnaire on obstetric events, maternal age refers to the age of the mother at delivery and parity as defined as the number of previous pregnancies that lasted >16 weeks.

The intervention protocol did not interfere with conventional policies to expel the placenta, but prescribed whether to inject the content of the ampule intraumbilically between 30 and 60 minutes after delivery after the addition of saline solution to a volume of 20 ml. In the last instance (not to inject, i.e., group 3) the treatment was obviously not blinded to the clinician. In the first instance the unmarked ampule either contained 10 IU oxytocin (Piton-S, Organon, Oss, The Netherlands) in 1 ml saline solution (group 1) or only 1 ml of saline solution (group 2). After mixing, the solution was injected into the umbilical vein, after which a hemostat was placed on the umbilical cord distal to the site of injection. To distribute the solution into the placenta the cord was "milked" backward after injection of the solution.

In group 3 an ampule containing 1 ml saline solution

was added to the box to equalize the weight of all boxes. However, this ampule was marked "Do not use. Throw away. Control."

Manual removal of the placenta was always performed after induction of general anesthesia. The decision for this surgical intervention was based solely on the clinical judgment of the obstetrician involved.

To investigate possible fetomaternal transfusion associated with umbilical cord injection, two maternal serum samples were taken from a subset of 51 women from groups 1 and 2 for the determination of α-fetoprotein (AFP) levels.[5] The first sample was taken immediately before the intraumbilical injection and the second sample was taken shortly after expulsion of the placenta. Serum AFP concentrations were analyzed with an enzyme-labeled immunoassay (Abbott AFP EIA Monoclonal, Abbott, Amstelveen, The Netherlands).

In all contributing hospitals, total blood loss was noted in a standardized way: during the third stage as much blood as possible was collected in a basin and subsequently measured. Moreover, spill in the sheets was estimated and added to the measured volume.

Duration of pregnancy was based on the last menstrual period if preceded by three normal cycles and if not different by >1 week from a fetal measurement by ultrasonography before 18 weeks, in which case the ultrasonographic measurement was used for its calculation.

Statistical analyses. The results are presented as means, medians, or proportions where appropriate. The dichotomous variable denoted "manual removal of the placenta" was used as the end point of prime interest. To determine whether the population means were all equal, the analysis of variance method was used for continuous variables (maternal age, gestational age, duration of second stage, birth weight, and placental weight).[6] The χ^2 tests were used for dichotomous variables and the Kruskal-Wallis test for variables that were not normally distributed (time interval from injection to spontaneous expulsion of placenta, blood loss). Serum AFP values before and after injection were tested by the Wilcoxon signed-rank test because the interindividual variance of the serum AFP values was very large and not normally distributed. A p value <0.05 was regarded to be significant. Approximation to the 95% confidence interval for proportional values was calculated with the formula described by Armitage[7]:

$$P \pm 1.96 \sqrt{(pq/n)}$$

Results

From the total sample of 220 women who were recruited for the trial, 20 women (9.1%) were excluded from the analyses because of violations of the treatment protocol. Reasons for exclusion were delivery at a pregnancy duration of <28 weeks ($n = 2$), the possible erroneous administration of saline solution from the ampule instead of the requested nontreatment in group 3 ($n = 10$), untimely injection in groups 1 or 2 ($n = 6$), and questionnaires that did not mention the time and way of expulsion of the placenta ($n = 2$). Hence, the final sample comprised 200 women with retained placenta, 72 of whom where randomized to oxytocin treatment (group 1), 69 to placebo treatment (group 2), and 59 to nontreatment (group 3). More than 75% of the women were white, about 10% were of African descent, and the remainder were of mixed Asian (5%) or Mediterranean (7%) origin. No statistical differences existed among these and other characteristics of the three groups (Table I).

No differences between the oxytocin group and the

placebo group could be found in the proportion of placentas expelled spontaneously before injection (8% and 10%, respectively) or after injection (both 54%), the injection being given in both groups at a median interval of 45 minutes after delivery of the infant. However, a small but significant difference between both groups was found in the median time interval from injection to spontaneous expulsion of the placenta (Table II). The frequencies of manual removal of the placenta, the major end point of the study, did not differ significantly among all groups and neither did the median volume of blood loss. In practice with the final groups, after exclusion, the power to detect a 30% reduction in the rate of manual placenta removal between the oxytocin and placebo group with $\alpha < 0.05$ was 80%.

In 51 women (25 of group 1 and 26 of group 2) blood samples taken both before injection and after expulsion of the placenta were assayed for AFP. Serum AFP levels did not increase as a result of the intraumbilical injection, but on the contrary a slight decrease was found when each first sample was compared with the second one (medians, 76 and 73.5 μg/ml for the first and second samples, respectively; $p < 0.001$).

Comment

Our study did not show a beneficial effect of the intraumbilical administration of 10 IU oxytocin in 20 ml of saline solution in women with retained placenta apart from a minor reduction in time between injection and spontaneous expulsion of the placenta when oxytocin was given rather than saline solution only. On the contrary, blood loss appeared lowest, although not significantly, in the nontreated control group as compared with the oxytocin-treated group. Because it appeared from the answers to the questionnaire that in the nontreated group an ampule that contained saline solution was injected instead of thrown away, 10 women in this group were excluded from the study. However, six of these 10 women eventually had to have manual placenta removal. When these women were left in the study, the median amount of blood loss in the control group amounted to 800 ml. When the women were added to the placebo group the median amount of blood loss in this group rose to 825 ml. However, in both options no significant difference in the rate of manual placenta removal or in the amount of blood loss among the three groups was obtained.

In fact, the findings of this study are made within the context of obstetric care of the contributing Dutch hospitals and therefore caution should be exercised to extrapolate the results to other populations groups. For instance, the mean age of the study population was >28 years, which is probably high as compared with many other countries. However, the reason for this is not only that more and more Dutch women start a family after completion of their education, but also that manual removal of the placenta more often occurs when age increases. In the period January 1988 to October 1990 in the Academic Medical Centre, the mean age of all women with placenta retention ($n = 292$) was 30.9 ± 0.3 SEM years and without placenta retention ($n = 4959$) 27.8 ± 0.1 years.

Apart from Golan et al.[3] in 1983, several others studied the effect of intraumbilical vein administration of oxytocin.[8-14] To examine the efficacy of this management for retained placenta a randomized placebo-controlled study design is imperative. To date we are aware of only two Danish studies[11, 14] and one English study[15] that made use of this approach. In the first study,[11] a single blind study that involved 51 women randomly allocated to the three treatment groups, no effect of intraumbilical oxytocin (10 IU diluted in 10 ml of saline solution) could be demonstrated on the rate of manual removal of a retained placenta. In the second study, Wilken-Jensen et al.[14] described their

findings of a randomized controlled trial that involved 37 women with a retained placenta. Women allocated to the treatment group (n = 18) were given 100 IU of oxytocin (10 times the dose used by Golan et al.[3] and us) into the umbilical vein. Five of 18 women (28%) in the oxytocin group and 11 of 19 women (58%) who received normal saline solution had to have manual removal of the placenta (not significant). The study by Selinger et al.,[15] which comprised 30 women, did not show an effect of oxytocin.

To determine whether intraumbilical injection of oxytocin shortened the third stage of labor Chestnut and Wilcox[12] and Young et al.[13] conducted a controlled trial in which 10 IU oxytocin in 20 ml of saline solution was administered immediately after delivery of the child. They could not show any effect of the therapy. The small sample size in all these studies could have obscured an effect on the rate of manual removal of the placenta by the intraumbilical injection of oxytocin.

The clinically irrelevant decrease in serum AFP levels in individual women in the interval from the time of injection to after the expulsion or manual removal of the placenta can only be explained by the decrease normally seen after parturition.[16]

In conclusion, this is the first study of which we are aware on women with a retained placenta that evaluates the efficacy of intraumbilical vein administration of oxytocin by the method described by Golan et al.[3] with a randomized, double-blind, placebo-controlled trial design. The benefit of the method appears to be very doubtful because no effect of the intraumbilical vein administration of oxytocin on the relative frequency of manual removal of the placenta or on the amount of blood loss could be demonstrated.

We thank Hans Oostink and Kathryn Waters for their statistical advise, David Carmichael for his assistance with computer programming, Marianne Paul for performance of the AFP analyses, and Dries van der Meulen for his support. We thank Organon and the pharmacy of the Academisch Medisch Centrum, respectively, for the supply and packing of oxytocin and placebo ampules used in this study. We especially thank all the pregnant women who participated in the study.

Collaborating hospitals in the study are Amsterdam, Academisch Medisch Centrum (K. Boer), Boven IJ Ziekenhuis (P.H.S. Wassenberg), Onze Lieve Vrouwe Gasthuis (M.F. Schutte), and Burgerziekenhuis (G. Kleiverda); Amstelveen, Ziekenhuis Amstelveen (J.G. van der Pol); Utrecht, Academisch Ziekenhuis Utrecht (H.W. Bruinse); Zaandam, Ziekenhuis 'De Heel' (J.W. van der Slikke); Zwolle, Ziekenhuis de Weezenlanden (A.L. Troostwijk).

The role of the transcerebellar view in the detection of fetal central nervous system anomaly

Lyndon M. Hill, MD, Jerry G. Martin, MD, Joanne Fries, RDMS, and Joyce Hixson, RDMS

Pittsburgh, Pennsylvania

The current resolution of antenatal ultrasonography permits the sonologist to visualize and critically evaluate the cerebellum and cisterna magna. Abnormalities in the size and shape of these structures will assist the sonologist in the detection of the majority of central nervous system malformations. (Am J Obstet Gynecol 1991;164:1220-4.)

Key words: Cerebellum, central nervous system anomalies

In 1974, ADR Ultrasound introduced the first commercial real-time B-scan linear array system. With improvements in resolution, finer anatomic detail can be appreciated while at the same time reducing the overall time required for a thorough fetal survey. By 1980, it was estimated that one third of all pregnant women in the United States had had an ultrasonographic examination before delivery. Currently in some countries, 90% to 100% of obstetric patients will have their pregnancy evaluated ultrasonographically. The complex issues of availability, physician training and expertise, and cost are beyond the scope of this article. We would, however, like to address the component parts of an acceptable obstetric ultrasonographic examination of fetal intracranial anatomy. A review of the literature as well as our experience with the transcerebellar view leads us to propose that the cerebellum and cisterna magna should be documented in every fetal anatomic survey after 15 weeks' gestation.

Embryologic development

The cerebellum is derived from neuroblasts on either side of the rhombencephalon beneath the fourth ventricle. By 8 weeks' gestation, cells from the two sides begin to fuse in the midline. The characteristic shape of the cerebellum is a result of the differential growth of its hemispheres in contrast to the median vermis.[1] Ultrasonographically, the transverse cerebellar diameter is consistently visualized after 15 weeks' gestation.

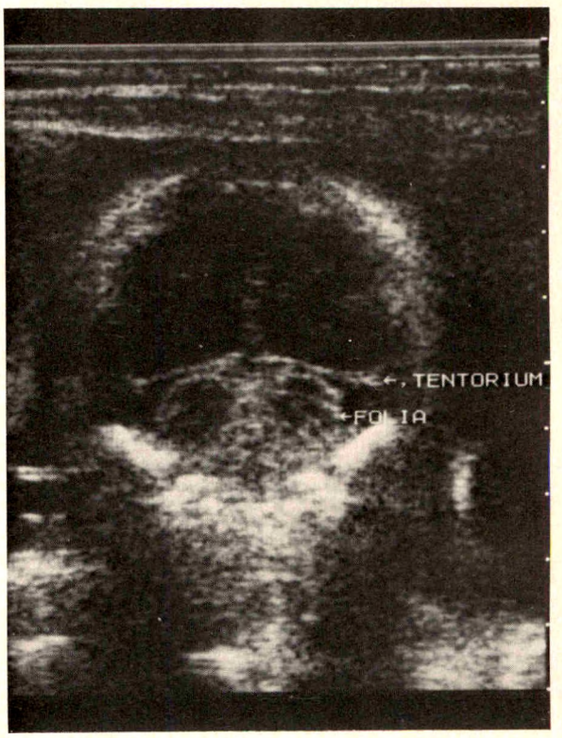

Fig. 1. Coronal view of the cerebellum (26 weeks' gestation). Folia of the cerebellar hemispheres and the tentorium can be visualized.

The cerebellar folial patterns can be appreciated with high resolution real-time scanning (Fig. 1).

Cerebellar function

In general, the cerebellum coordinates both reflex and voluntary motor function. Because the cerebellar hemispheres are phylogenically younger than the mid-

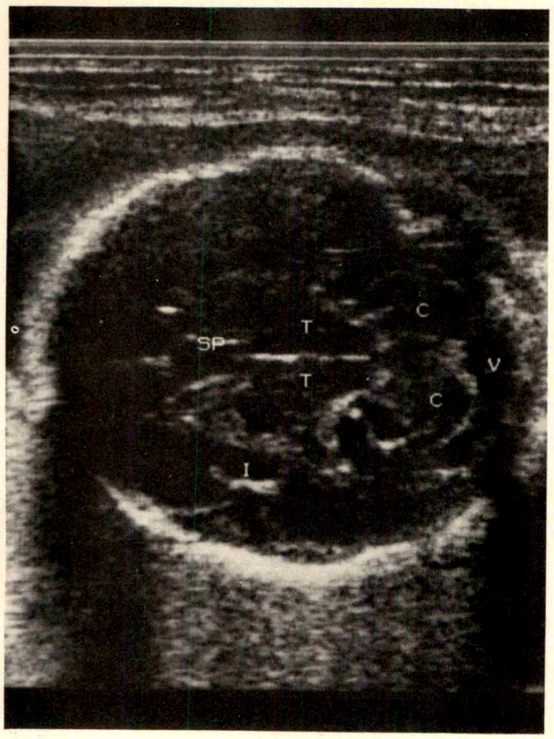

Fig. 2. Axial view of the cerebellar hemispheres *(c)*. The septum pellucidum *(sp)*, thalami *(t)*, insula *(i)*, and echogenic vermis *(v)* within the cisterna magna are also visualized at this level.

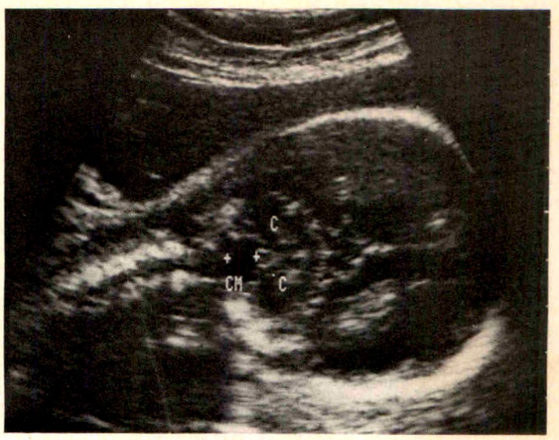

Fig. 3. Graticules indicate the cisterna magna *(cm)* immediately behind the cerebellar vermis (*c*, cerebellar hemispheres).

Fig. 4. *Arrow* demarcates the occipital sinus.

line vermis, the types of motor activity controlled by these areas are different. The cerebellar hemispheres have a primary role in posture and gait, whereas the vermis governs ocular movements. Both areas of the cerebellum contribute to memory, motivational behavior, and learning.[1]

Anatomic-ultrasonographic correlation

The cephalic portion of the cerebellum is immediately posterior to the thalami. The folia of the anterior and quadrangular lobule can also be appreciated on this view. The cerebellar hemispheres, vermis, and cisterna magna can be documented with a slightly greater posterior angulation of the transducer (Fig. 2). An infolding of the dura mater, the tentorium cerebelli (Fig. 1), separates the cerebellum from the cerebrum.

The cisterna magna (Fig. 3) is part of the subarachnoid space that results from the arachnoid bridging between the medulla oblongata and the caudal aspect of the cerebellum. The depth of the cisterna magna is 5 ± 3 mm after 15 weeks' gestation.[2] Occasionally a tubular structure (Fig. 4) is visualized within the cisterna magna. This has been labeled the straight sinus by Mahony et al.[2] and the torcular Herophili (confluence of the sinuses) by Pilu et al.[3] Anatomically, the straight sinus and the torcular Herophili are located at the junction of the falx cerebri with the tentorium cerebelli (i.e., above the plane of the cerebellar hemispheres). Hence the structure visualized within the cisterna magna is most likely the occipital sinus.

Congenital anomalies

Central nervous system anomalies are among the most frequent anomalies encountered by the sonologist. Whereas the diagnosis of anencephaly is not technically difficult, spina bifida as well as infratentorial anomalies are often harder to appreciate.

Nicolaides et al.[4] were the first to emphasize the importance of the intracranial abnormalities associated

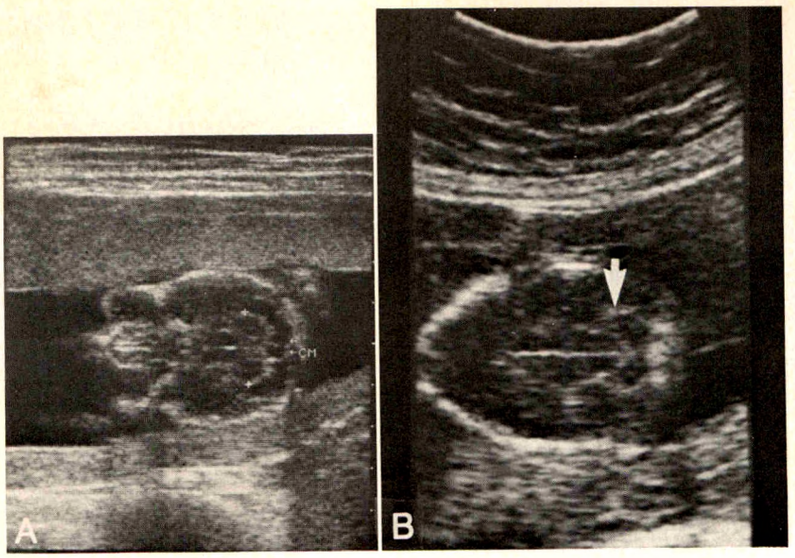

Fig. 5. Axial view of the cerebellum at 18 weeks' gestation. **A,** Normal cerebellum (between the graticules) and cisterna magna *(cm)*. **B,** Banana-shaped cerebellum *(arrow)* and the absence of the cisterna magna in a fetus with a neural tube defect.

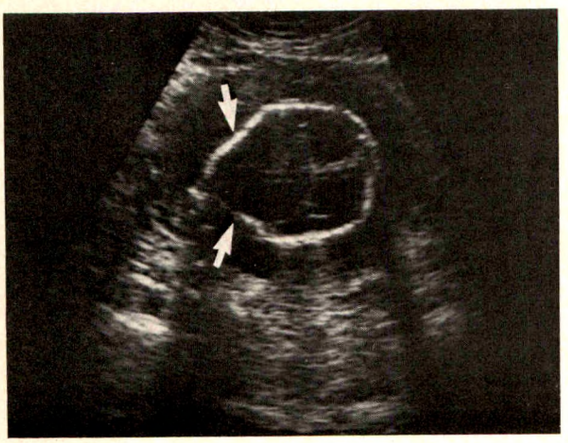

Fig. 6. Axial view of the skull in a fetus at 20 weeks' gestation with a neural tube defect. Scalloping of the frontal bones (lemon sign, *arrows*) is present.

with spina bifida. The cerebellum, in the majority of instances, is deviated into the cisterna magna (banana sign). Consequently, the cisterna magna is virtually obliterated (Fig. 5, *A* and *B*).[5] Scalloping of the frontal bones (lemon sign) (Fig. 6) is a second cranial sign associated with spinal bifida.[4] Finally, the transverse cerebellar diameter in fetuses with spinal bifida is characteristically ≥2 SD below the mean for gestational age.[6] It must be emphasized that the presence or absence of a banana-shaped cerebellum, effacement of the cisterna magna, or lemon-shaped calvarium should not be considered a substitute for a careful evaluation of the fetal spine.

Cerebellar abnormalities are frequently associated with chromosomal anomalies. In the infant with Down syndrome, total brain weight is reduced by 24% and cerebellar weight is decreased by 34%.[7] Therefore we evaluated the transcerebellar diameter in 23 fetuses with Down syndrome between 15 and 20 weeks' gestation to determine whether this measurement could be used as ultrasonographic marker for this particular chromosomal abnormality. The transcerebellar diameter was within the normal range for the cases that were evaluated. These results indicate that either the transcerebellar diameter is insufficiently sensitive to detect the reduction in cerebellar weight or that with Down syndrome the processes that result in cerebellar hypoplasia occur after the second trimester.

Thurmond et al.[8] have reported five cases of trisomy 18 with an enlarged cisterna magna. The transverse cerebellar diameter in these cases were all >2 SD below the mean. Nakamura et al.[9] also detected cerebellar hypoplasia (Fig. 7) in all nine cases of trisomy 18 evaluated between 33 weeks' gestation and 6 months of age. In a retrospective study of 19 trisomy 18 fetuses at our institution, the transcerebellar diameter was ≥2 SD below the mean for gestational age in 11 (57.9%) (unpublished data). The likelihood that the transverse cerebellar diameter would be ≥2 SD below the mean increased with gestational age—two of seven fetuses (28.6%) before 21 weeks' gestation versus nine of 12 (75%) third-trimester fetuses had a cerebellar diameter

Fig. 7. Cerebellar hypoplasia is evident at 35 weeks' gestation in this fetus with trisomy 18.

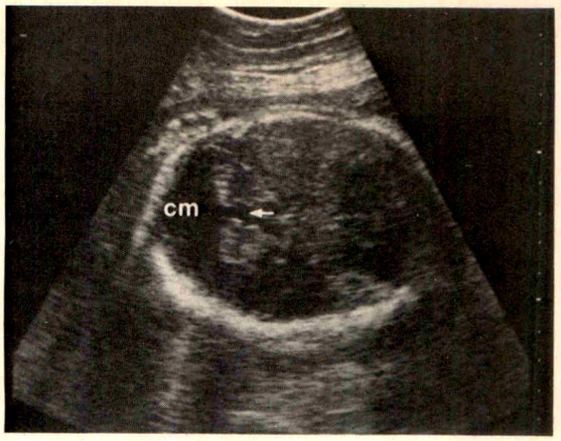

Fig. 8. Dandy-Walker anomaly at 31 weeks' gestation. The cisterna magna *(cm)* is enlarged and the vermis is absent. *(Arrow,* Region of vermis.)

>2 SD below the mean. Two of four fetuses with trisomy 18 that were normally grown at the time of the ultrasonographic examination had a normal transverse cerebellar diameter and two had cerebellar hypoplasia. In contrast, six of 15 fetuses with trisomy 18 that were affected by intrauterine growth retardation had a normal transverse cerebellar diameter whereas the remaining nine fetuses had a transverse cerebellar diameter ≥2 SD below the mean. Hence either an inherent abnormality in brain growth or generalized growth inhibition may give rise to the increased frequency of cerebellar hypoplasia in fetuses with trisomy 18.

Although cerebellar hypoplasia has also been described with trisomy 13, holoprosencephaly is a much more frequent finding.

Cerebellar hypoplasia may be inherited (autosomal recessive).[10] Other causes of cerebellar hypoplasia include viral infection,[11] exposure to teratogens,[12] in utero hypotensive brain stem necrosis,[13] and endogenous factors that alter the bony structure of the posterior fossa.[14]

Cerebellar agenesis may be complete or incomplete. Whereas complete agenesis is extremely rare, incomplete agenesis may occasionally be present without any detectable signs or symptoms.[15] In 1969 Joubert et al.[16] originally described five children with agenesis of the cerebellar vermis associated with ataxia, abnormal eye movements, and mental retardation.

The Dandy-Walker anomaly consists of complete or partial absence of the vermis, a posterior fossa cyst continuous with the fourth ventricle, and in the majority of cases, hydrocephalus (Fig. 8). This malformation is a result of a developmental arrest in the hindbrain that occurs before the third fetal month. Antenatal detection is therefore possible in the latter part of the second trimester. Occasionally the typical ultrasonographic signs of a Dandy-Walker malformation do not become apparent until the third trimester.[17]

An arachnoid cyst will enlarge the cisterna magna, but is not associated with a vermis defect or other cerebellar abnormalities.[2] However, a posterior fossa arachnoid cyst cannot always be distinguished from a Dandy-Walker malformation on antenatal ultrasonography.

It should be remembered that a prominent cisterna magna may be a variant of normal. Similarly, a slightly enlarged or decreased transverse cerebellar diameter may not indicate central nervous system disease, particularly in the third trimester when an accurate measurement can be difficult to obtain.

The American College of Obstetricians and Gynecologists[18] has considered an assessment of the lateral ventricles as well as a transcerebellar view as part of a midpregnancy anatomic survey. Filly et al.[19] evaluated not only the atrium of the lateral ventricle and the cisterna magna, but also the cavum septum pellucidum, as a means of screening for central nervous system malformations. They found that the atrium of the lateral ventricle was enlarged (>10 mm) in 99 of 112 (88%) fetuses with a central nervous system anom-

aly, and seven of the remaining fetuses had an abnormal cisterna magna (<2 mm or >11 mm); the absence of the cavum septum pellucidum did not improve the 95% sensitivity of the other two observations. Our review, and the results of Filly et al.[19] suggest that by incorporating the transcerebellar view in all second- and third-trimester obstetric ultrasonographic examinations, the detection rate of central nervous system anomalies will be improved.

CA 125 levels in abruptio placentae

Barry R. Witt, MD, Rachel Miles, MD, Gordon C. Wolf, PhD, MD, George T. Koulianos, MD, and Ian H. Thorneycroft, PhD, MD

New Orleans, Louisiana

The diagnosis of abruptio placentae is frequently difficult despite ultrasonography; additional diagnostic parameters would be useful. Maternal serum CA 125, which is believed to derive from the decidua, is elevated in the first trimester and immediately after delivery when placental separation occurs, possibly because of decidual disruption. Serum CA 125 was measured in 27 patients beyond 20 weeks' gestation who were first seen with vaginal bleeding and in 17 control patients of similar gestational age and labor status. Mean (±SD) CA 125 levels were higher ($p < 0.01$) among patients with abruptio placentae (105.9 ± 115 U/ml) than among those with alternate sources of bleeding (13.7 ± 10 U/ml) or control patients (18.2 ± 11.7 U/ml). Mean (±SD) serum CA 125 levels in seven control patients within 6 hours post partum (194 ± 80.5 U/ml) were higher than those among patients first seen with abruptio placentae ($p < 0.01$). Sensitivity and specificity of CA 125 for abruptio placentae were 70% and 94%, respectively. Our data support a decidual source for CA 125 and may indicate utility of CA 125 as a marker for abruptio placentae. (Am J Obstet Gynecol 1991;164:1225-8.)

Key words: Serum CA 125, abruptio placentae

The incidence of abruptio placentae ranges from 0.49 to 1.5% of all deliveries with a perinatal mortality rate of 25% to 60%.[1] Although severe cases of abruptio placentae are characterized by the classic presentation of vaginal bleeding, abdominal or back pain, uterine tenderness, and signs or symptoms of hemorrhagic shock, the milder and more common forms may be difficult to diagnose with certainty. In general, the diagnosis is clinical; however, adjunct evaluation with ultrasonography to rule out placenta previa and identify large retroplacental hematomas may be helpful. That the diagnosis is primarily a clinical one was confirmed in a prospective study[2] in which only one of 59 cases of abruptio placentae were diagnosed by ultrasonography.

Additional noninvasive parameters to assist in the antepartum diagnosis of abruptio placentae would be extremely useful. Previous studies looked at other biochemical parameters to predict abruptio placentae. Salem et al.[3] described elevated levels of placental protein 5 in the serum of five of 12 women with abruptio placentae that were most striking in severe cases. These findings were not confirmed in an apparently similar clinical group.[4] It was also suggested that pregnancy-associated plasma protein A might be predictive of the occurrence of antepartum hemorrhage,[5] but this was not confirmed in a later study.[6]

CA 125, an antigenic determinant associated with ovarian carcinoma, is elevated in maternal serum with peaks detected in the first trimester[7, 8] and in the immediate postpartum period.[7] The origin of CA 125 in pregnancy is uncertain, although recent reports implicated the maternal decidua.[7, 9-14] The aforementioned CA 125 peaks were hypothesized to result from chorionic villi invasion of the decidual cells during early gestation and mechanical destruction of decidual cells during placental separation after delivery.[7] Such decidual disruption would also explain the elevated levels of CA 125 found in the serum of women 1 hour after second-trimester abortion.[7]

The elevation in levels of serum CA 125 after the separation of the placenta led to the current hypothesis that CA 125 may be elevated in pregnancies complicated by abruptio placentae. This preliminary study was undertaken to confirm that hypothesis and to determine whether CA 125 might be useful in the diagnosis of abruptio placentae.

Material and methods

Twenty-seven patients who came to the labor and delivery unit at Charity Hospital of New Orleans with vaginal bleeding after 20 weeks' gestation were included in the study. An additional 17 control patients who were past 20 weeks' gestation were recruited. On arrival at the labor and delivery unit, Institutional Review Board–approved informed consent was obtained and blood was drawn from an antecubital vein. Seven

†$p < 0.01$, Postpartum controls versus abruptio placentae.

of the control patients also had blood samples taken within 6 hours post partum. The serum was separated and was frozen at −20° C until assayed. All specimens were obtained between July and December 1989. All assays were run in duplicate and simultaneously to obviate interassay variability.

The CA 125 assay (Centocor, Inc., Malvern, Pa.) used antibody-coated beads and iodine 125–labeled antibody in a solid phase "sandwich" radioimmunoassay. The reference standard was that maintained by the manufacturer. The sensitivity at the lower range of the standard curve was increased by the use of additional dilutions of the standards as described by Pittaway.[15] The intraassay and interassay variations were 5.4% and 7.2%, respectively.

Clinical diagnosis of abruptio placentae was made according to the criteria outlined by Hurd et al.[2] In every case, diagnosis of placenta previa was excluded by ultrasonography, and at the same time, evidence of retroplacental or retrochorionic hematoma was sought. The diagnosis of abruptio placentae was confirmed at delivery in each case with either gross examination of the placenta revealing a firmly adherent retroplacental clot with disruption of the underlying tissue, pathologic diagnosis, or both.

Statistical analysis was performed with analysis of variance, Newman-Keuls tests, and χ^2 analysis. Sensitivity and specificity were calculated with the standard CA 125 cutoff level used for ovarian cancer (>35 U/ml).[16]

Results

The demographics of the study and control groups are summarized in Table I. There are no significant differences between the three groups with regard to maternal and gestational ages or labor status. Gravidity was significantly greater in the group with abruptio placentae, which reflects the higher incidence of abruptio placentae in multigravid women. There were three stillbirths in the study group, all of which were among the patients with abruptio placentae. Despite the differences in gravidity and number of stillbirths, the groups studied are comparable with regard to gestational age, maternal age, and number in labor.

Table II summarizes the serum CA 125 levels of the two groups and of the subdivisions of the study group. Of note are the significantly higher levels of CA 125 in the patients with abruptio placentae ($p < 0.01$) than in the control patients or in patients with other causes of bleeding. The patients with placenta previa tended to have lower levels of serum CA 125 than those of the control group (not significant). Among the patients with other causes of bleeding, one patient had cervical condylomas, one had cervical incompetence, two had low-lying placentas, and the remaining seven had indeterminate causes. In three patients with fetal death, serum CA 125 levels were 23.1, 97.5, and 283.9 U/ml.

There was no correlation between gestational age and serum CA 125 ($r = 0.13$). In addition, there was no difference in mean (±SD) CA 125 levels between all patients in labor (48.6 ± 81 U/ml) and patients not in labor (16.9 ± 13 U/ml).

The mean CA 125 level in the seven control patients who had serum sampled within 6 hours of delivery was significantly higher than the first CA 125 levels measured in the patients with abruptio placentae ($p < 0.01$).

Fig. 1 shows the individual CA 125 levels for each patient.

The sensitivity and specificity for CA 125 in the diagnosis of abruptio placentae were 70% and 94%, respectively.

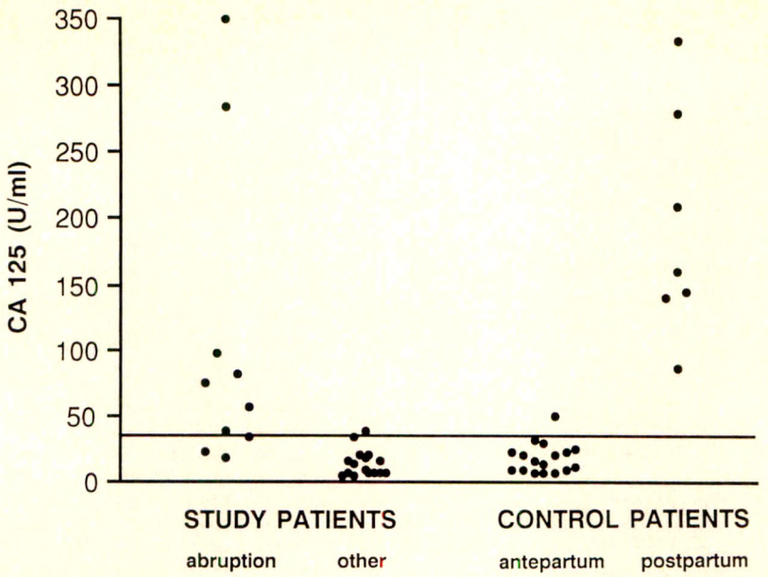

Fig. 1. Individual serum CA 125 levels (units per milliliter) in study patients (abruptio placentae and other causes of bleeding) and control patients (antepartum and post partum). Horizontal line represents serum CA 125 cutoff of 35 U/ml.

Comment

The origin of CA 125 in pregnancy is unclear. The CA 125 antigenic determinant is associated with a glycoprotein with a high molecular weight that is expressed in coelomic epithelium during embryonic development, including müllerian epithelium and the lining of the peritoneum, pleura, and pericardium.[17] Thus the developing fetus was implicated as the source of CA 125 in pregnancy. However, the absence or low level of the antigen in fetal urine and cord blood make this unlikely.[9, 11]

CA 125 was found in high levels in amniotic fluid[9, 11, 18] and it was proposed that CA 125 in the amniotic fluid is produced by the amnion,[11, 13] chorion,[9] or decidua.[12, 13]

There are several reports that support the decidua as the major source CA 125 in maternal serum. Thus high tissue levels of CA 125 were found in first-trimester decidual homogenates[7, 14] and extracts from term decidua.[9] With the use of immunohistochemical staining, CA 125 was localized to the cytoplasm of decidual cells and amnion epithelial cells, but not to the chorion and placental tissue.[13] However, in another study CA 125 was detected in all epithelial cells of the placenta and extraplacental amniotic membranes, both in early gestation and at term.[11] First-trimester decidual cultures[10] and cell cultures from term amnion tissue[19] were shown to produce CA 125 in vitro. It was suggested that although the amnion cells contribute to the high levels of CA 125 in amniotic fluid, the maternal serum CA 125 is derived from decidual production.[7, 11, 14]

The potential of CA 125 as an indicator of abruptio placentae versus other causes of vaginal bleeding in the latter half of pregnancy is supported by review of the cause of these disorders. Abruptio placentae is initiated by hemorrhage into the basal decidua. The decidua then splits, leaving a thin layer adherent to the myometrium.[20] In comparison, one factor in the development of placenta previa is said to be defective vascularization of the decidua.[20] Therefore, it seems reasonable that abruptio placentae with concomitant decidual disruption leads to elevated levels of CA 125, whereas placenta previa, which involves poorly vascularized decidua, might be expected to result in lower levels of CA 125. Our data support this hypothesis and our finding of elevated postpartum CA 125 levels confirm the previous work of Kobayashi.[7] The finding of higher levels of CA 125 in normal postpartum patients than in patients with antepartum abruptio placentae supports the concept of decidual disruption as a cause of CA 125 release in that there are higher levels after complete separation of the placenta (i.e., at delivery) than after partial separation of the placenta (in abruptio placentae).

Previous reports[21, 22] described elevations of CA 125 in cases of intrauterine fetal death but previous studies looked primarily at gestations before 20 weeks. In our study all patients were past 20 weeks' gestation, with a mean (±SD) serum CA 125 level of 134.8 ± 109

U/ml among the intrauterine fetal death patients. However, CA 125 was not elevated in all cases of intrauterine fetal death; one of the patients had a CA 125 level of only 23.1 U/ml. It was suggested that in intrauterine fetal death the CA 125 originates in the destroyed decidua and not in the fetus itself.[7]

With the use of a clinical grading system for abruptio placentae outlined by Sher,[23] with mildest abruptio placentae graded 1 and most severe abruptio placentae graded 3, we classified zero, seven, and three patients as grade 1, 2, and 3, respectively. The mean (±SD) CA 125 levels in patients with grades 2 and 3 were 93.6 ± 115 U/ml and 134.8 ± 134 U/ml, respectively. Thus we were unable to confirm a significant correlation between severity of abruptio placentae and level of CA 125.

The current results suggest that maternal serum CA 125 may have clinical use in the diagnosis of abruptio placentae. Excellent specificity and encouraging sensitivity are noted. Furthermore, CA 125 may have use in the expectant management of gravid women with abruptio placentae, particularly those with significant prematurity.[1] Because the number of patients studied thus far is small, these data must be considered preliminary and additional study is required to corroborate these findings.

In summary, among 27 patients first seen with vaginal bleeding after 20 weeks' gestation, the mean serum CA 125 level among the 10 patients in whom abruptio placentae was diagnosed was significantly higher than those in the other study patients or the control patients. Our findings are compatible with a decidual source for CA 125. These initial findings warrant further study of the utility of CA 125 as a diagnostic test for abruptio placentae or as a marker for following up premature patients being managed expectantly with mild abruptio placentae.

Management of severe preeclampsia detected in early labor by prostaglandin A_1 or dihydralazine infusions

Mokhtar K. Toppozada, MD, Emad Darwish, MD, and Azza A.T. Barakat, MS
Alexandria, Egypt

The presence of severe pregnancy-induced hypertension at the onset of labor requires therapy with a potent hypotensive agent. Prostaglandin A_1 is a powerful vasodepressor that augments renal blood flow and glomerular filtration and possesses antiplatelet aggregator and oxytocic properties. A continuous intravenous infusion of prostaglandin A_1 (40 to 50 μg/min) or dihydralazine (35 to 50 μg/min) was administered to 20 women with severe preeclampsia (10 in each group). The induced hypotensive response was similar with both drugs but the maximum reduction in blood pressure was achieved sooner with dihydralazine (4 hours) compared with prostaglandin A_1 (7.5 hours). The more gradual hypotensive response is probably less dangerous on placental perfusion than a sudden change. Moreover, the oxytocic property of prostaglandin A_1 shortened the time to delivery, which constitutes another potential advantage. (Am J Obstet Gynecol 1991;164:1229-32.)

Key words: Management of severe preeclampsia, labor, prostaglandin A_1, hydralazine, hypotensive agents

Hypertensive disorders in pregnancy are relatively common complications of gestation and form one side of the great triad of complications (hemorrhage, hypertension, and sepsis) that are responsible for the majority of maternal deaths. Pregnancy-induced hypertension occurs in about 5% to 15% of all pregnancies delivered in large obstetric centers.[1]

Over the past 10 years several studies from the University of Alexandria attempted to evaluate the effects of prostaglandin A_1 (PGA_1) infusions in severe cases of pregnancy-induced hypertension. The results of the investigations were encouraging in that a hypotensive response was elicited and renal functions were markedly improved.[2,3] Moreover, this compound induced a mild oxytocic response and was capable of inducing labor. Also, the weak antiplatelet aggregator property of this agent offered an additional advantage.[4] This beneficial group of responses (renal, cardiovascular, and uterine) appeared to offer a promising potential in clinical practice among subjects not in labor and pregnant >35 weeks.[2-7]

Hydralazine hydrochloride is a well-known, effective antihypertensive agent. Most authorities concur that it is the agent of choice for the treatment of severe pregnancy-induced hypertension. When hydralazine was used in human beings a fall in blood pressure and in total peripheral resistance was found inasmuch as it exerts a direct vasodilator effect on peripheral arterioles. It improved uterine circulation and has a beneficial effect on cerebral, retinal, and renal circulation in pregnancy.[8]

The aim of this work was to evaluate the clinical use of PGA_1 as an antihypertensive agent and as a weak oxytocic agent in patients with severe preeclampsia who were in early labor. The clinical performance of this drug was compared with that achieved with another hypotensive drug, hydralazine, in a similar group of patients.

Patients and methods

This study comprised 20 pregnant patients with gestational ages that ranged from 28 to 40 weeks. All patients had the manifestations of severe preeclampsia (i.e., with a systolic blood pressure ≥160 mm Hg or a diastolic blood pressure ≥110 mm Hg at bed rest). Edema and proteinuria were present in all patients.

The general condition was evaluated, and whenever possible it was confirmed by history and examination that these patients did not originally have essential hypertension or chronic nephritis. Patients with bronchial asthma, glaucoma, and severe systemic disorders were excluded.

The obstetric examination was within normal limits, with vertex presentation and adequate cephalopelvic relationship. The examination and tocographic findings confirmed that the patients were in early labor by regular, rhythmic uterine contractions (three contractions per 10 minutes) accompanied by effacement and dilatation of the cervix. Moreover, there was formation

of the bag of forewaters if the membranes were not ruptured. The cervix was dilated to <5 cm. The case material was divided at random with a computer-generated table into two groups according to the specific therapy that was used.

Group I. Ten patients were given PGA_1 infusions (kindly provided by Prof. Sune Bergstrom, Karolinska Institute, Stockholm, Sweden) in a dose of 40 to 50 μg/min, which is equivalent to the recommended dose of 0.5 μg/kg per minute for women who weigh 80 to 100 kg.

Group II. Ten patients (controls) were given dihydralazine (Nepresol antihypertensive agent, Ciba-Geigy, Basel, Switzerland) infusions in a dose of 35 to 50 μg/min.

Apart from sedation with diazepam, none of the subjects selected for the present investigation received any other medication.

PGA_1 was available in vials; each vial contained 3 ml (10 mg/ml). The infusion was prepared by adding 2 to 2.5 ml of PGA_1 into 500 ml bottles of 5% glucose (40 to 50 μg/ml); infusion pumps were used to provide the precalculated dose of 1 ml/min.

Dihydralazine was available as Nepresol antihypertensive agent in powder form in ampules of 25 mg, plus ampules of 2 ml solvent. The infusion was prepared by adding one ampule of dihydralazine and one ampule of the solvent into 500 ml bottles of 5% glucose (50 μg/ml).

Before and during infusion and until delivery occurred, the following parameters were carefully monitored: (1) blood pressure was continuously monitored with the Dinamap vital sign monitor (Critikon, Inc., Tampa, Fla.); (2) uterine activity and fetal heart rate were also continuously monitored by external methods; (3) clinical course and progress of labor were followed up closely and any side effects or adverse reactions were recorded; (4) obstetric outcome and infusion-delivery period were assessed, measurement of blood pressure was continued for 48 hours after delivery, and clinical assessment of the neonates with Apgar scores at 1 and 5 minutes was performed.

Results

There were no significant statistical differences between the two groups with regard to the mean age, gravidity, parity, and gestational age. There were no differences in the level of systolic and diastolic blood pressures of the two groups or in the degree of cervical dilatation on admission (Table I).

Changes in blood pressure in the two groups. After the onset of the PGA_1 infusion in group I the systolic and diastolic blood pressure levels decreased gradually in all patients. The mean of the lowest recorded readings of systolic blood pressure achieved at various time intervals in different subjects was 142 ± 11.4 mm Hg. There was a highly significant reduction compared with admission values (Student's *t* test, 17.6; $p < 0.01$). The mean of the lowest diastolic pressure recorded during infusion was 92.5 ± 5.9 mm Hg, which was also significantly lower than admission values (Student's *t* test, 11.9; $p < 0.01$). At the onset of the PGA_1 infusion the mean arterial blood pressure (MAP) was 138.3 ± 5.6 mm Hg. During the period of the infusion the mean value of the minimum MAP (achieved at various time intervals) was 109 ± 7.4 mm Hg. The reduction in the MAP was highly significant (Student's *t* test, ±16.5; $p < 0.01$).

After the onset of the dihydralazine infusion in group II, the systolic and diastolic blood pressure levels decreased gradually in all patients. The mean of the lowest recorded readings of systolic and diastolic blood pressures were 130.5 ± 7.6 and 90.5 ± 5.0 mm Hg, respectively. There was a highly statistically significant reduction in systolic and diastolic blood pressure levels during treatment with dihydralazine infusion compared with admission values ($p < 0.01$).

During the period of dihydralazine infusion, the mean value of the minimum MAP achieved at various time intervals was 106.07 ± 9.5 mm Hg. The reduction in the MAP was also highly significant (Student's *t* test, 10.7; $p < 0.01$) (Fig. 1, Table II).

Forty-eight hours after delivery, the mean systolic/diastolic blood pressure levels were 137.0 ± 8.23/91.5 ± 5.30 in group I and 132.0 ± 4.22/90.0 ± 6.67 in group II. These values were statistically highly significant when compared with admission levels ($p < 0.01$) but not different from the minimum values recorded during infusion ($p > 0.05$). The time needed for the blood pressure to reach minimal levels during infusions is presented in Table III, which shows that the lowest recordings were achieved in a shorter time in group II.

Table II. Mean of the maximum reduction in blood pressure during infusions of PGA_1 or dihydralazine in groups I and II

	Group I		*Group II*	
	Maximum reduction	*t**	*Maximum reduction*	*t**
Blood pressure (mm Hg)				
Systolic	41.0 ± 7.38	17.6	50.0 ± 19.6	8.1
Diastolic	23.5 ± 6.26	11.9	31.0 ± 9.3	10.1
MAP (mm Hg)	29.3 ± 5.63	16.5	36.3 ± 10.8	10.7

*Compared with admisssion values, $p < 0.01$, Student's t test.

Table III. Mean time needed (hours) to reach minimum blood pressure after the onset of infusion in the two groups

Blood pressure	*Group I*	*Group II*	*t**
Systolic	7.6 ± 2.63	4.2 ± 1.32	3.654
Diastolic	7.5 ± 1.35	3.9 ± 1.26	6.164

*Significant, $p < 0.05$, Student's t test.

Changes in pulse rate. There was a significant increase in pulse rate in the two groups during infusion. The maximum values were achieved at various time intervals during infusion. In group I, the mean initial pulse rate (i.e., before starting the infusions) was 79.0 ± 6.1 beats/min, whereas the mean of the maximum pulse rate during infusion was 94.4 ± 5.9 beats/min (Student's t test, 7.9; $p < 0.01$). In group II the mean initial pulse rate was 79.8 ± 8.5 beats/min, whereas the mean of the maximum pulse rate was 84.4 ± 10.1 beats/min (Student's t test, 4.4; $p < 0.01$). By comparing the mean pulse rate of the two groups it was observed that there was a significant difference between group I and II (pooled Student's t test, 7.17; $p < 0.01$).

Course of delivery. In group I, the mean of the infusion delivery interval was 7.7 ± 3.1 hours, whereas in group II it was 10.12 ± 2.5 hours; the difference between both groups was significant (pooled Student's t test, 1.9; $p < 0.05$). The duration of labor among women who had vaginal deliveries in both groups (nine in group I and eight in group II, i.e., excluding women who had cesarean deliveries) were 7.49 ± 3.21 and 10.10 ± 1.34 hours, respectively (Student's t test, 2.13, $p < 0.05$).

In group I, eight patients were delivered spontaneously during PGA_1 infusions and 1 patient was delivered by vacuum extraction. A cesarean section was performed because of cervical dystocia and premature rupture of membranes in one patient. In group II, seven patients were delivered of infants spontaneously

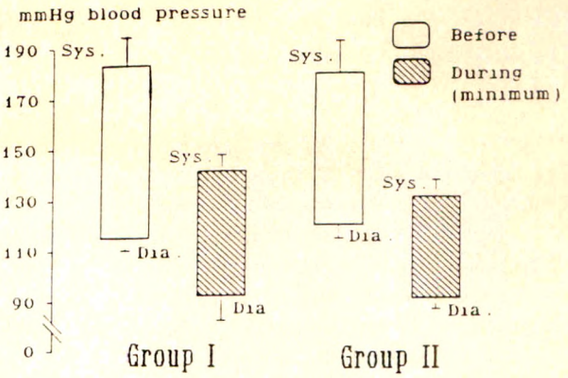

Fig. 1. Mean ± SD of systolic *(Sys.)* and diastolic *(Dia.)* blood pressure (mm Hg) in both groups before onset of infusions and mean of minimum level recorded during therapy.

during dihydralazine infusions and one patient was delivered by low forceps. Cesarean section was done because of fetal distress in one patient (severe bradycardia) and cephalopelvic disproportion in another patient.

In group I, fetal bradycardia was detected in one patient at various time intervals. The rest of the patients showed normal fetal heart rate patterns. In group II, phases of temporary bradycardia were recorded in three patients at various time intervals during infusion of dihydralazine. One of these patients was delivered by cesarean section because of fetal distress, whereas the others showed improved patterns on position change and oxygen inhalation. The rest of the patients showed normal patterns. There were no serious maternal side effects during infusion in both groups. All recorded side effects were temporary and were spontaneously relieved by decreasing the rate of infusions.

In group I, the mean of the Apgar scores at 1 minute was 9.2 ± 0.9 and 10 at 5 minutes, whereas in group II the corresponding figures were 9.2 ± 0.7 and 10, respectively. This shows that there was no difference in the Apgar scores of the two groups.

Comment

Hypertensive disorders are serious complications of gestation and constitute a major cause of maternal mortality. They also represent an important cause of perinatal mortality and severe morbidity.[6]

For many years the lines of therapy of preeclampsia depended on the control of the manifestations (edema, proteinuria, hypertension) and prevention of complications. In severe preeclampsia and in cases that do not respond to therapy, termination of pregnancy represents a life-saving procedure.

Recently, PGA_1 was clinically tested in the treatment of pregnancy-induced hypertension.[6, 7] The adminis-

tration of PGA_1 by intravenous drip in a dose of 0.5 μg/kg per minute induced a hypotensive response that is probably by means of peripheral arteriolar dilatation. It also augmented the renal blood flow, almost doubled glomerular filtration rate, and showed a weak uterine stimulatory effect in term pregnant women.[3, 5, 6]

It was later found that PGA_1 infusion alone was insufficient to induce labor in all treated patients, especially among subjects with unripe cervices. PGA_1 infusion together with ripening of the cervix with PGE_2 vaginal or cervical gel successfully induced labor within 24 hours in most of the patients.[7]

Dihydralazine group of drugs is known to improve kidney perfusion, may improve placental perfusion, and is effective in the reduction of premature births and still births.[9]

In the present work the aim was to use PGA_1 or dihydralazine to suppress the high blood pressure of severe preeclamptic toxemia to normotensive levels during the progress of spontaneous labor. The dose of PGA_1 infusion used was determined on the basis of previous experience with the same drug in Shatby Hospital.[5, 6] However, a fixed dose range of 40 to 50 μg/min was used in the present work, whereas in previous studies the dose was calculated according to the subject's weight (0.5 μg/kg per minute).

The two groups were comparable with respect to all admission criteria. Patients in both groups showed a good hypotensive response. Also, there was no rebound rise in blood pressure after delivery. This is probably because of the proper selection of the patients without any element of essential hypertension. The more gradual reduction of blood pressure in group I is less likely to decrease the uteroplacental perfusion than the rapid drop in blood pressure observed in group II.

The infusion-delivery interval was calculated from the time of starting the intravenous infusions, and it was significantly longer in group II with the use of dihydralazine than that in group I with PGA_1. This difference is an obvious advantage and is in agreement with the observation that PGA_1 is a uterine stimulant and has the ability to induce labor in term pregnant women.[2, 6, 7, 10]

All neonates in the two groups had good Apgar scores. The fetal heart rate changes during PGA_1 and dihydralazine infusions were generally temporary, and within the expected range of occurrence in severe cases of preeclampsia or placental insufficiency. These results are reassuring that the treatment used may not increase the fetal risks in such serious cases. However, some studies showed that patients with severe pregnancy-induced hypertension who received hydralazine had a significantly higher incidence of fetal distress than that of those who did not receive the drug.[11] In group I, the cesarean section rate (one of 10 patients) was relatively low and rather similar to previous studies with PGA_1.[5]

Comparison of the two lines of treatment in the present study shows both offered a good hypotensive response with no obvious serious side effects. With PGA_1 infusion, the reduction in blood pressure was more gradual and needed more time to reach its lowest level than that in group II with dihydralazine. Rapid reduction may compromise the fetus by decreasing the uteroplacental perfusion, but it may offer an advantage during the stress of an ongoing labor. PGA_1 infusion offers a shorter mean duration of infusion-delivery interval in view of its uterine stimulating property. This may represent another advantage to both mother and fetus.

The intrauterine probe electrode

Thomas H. Strong, Jr., MD,[a, b] Richard H. Paul, MD,[a, b] George D. Park,[a, b] Yi Cheng, PhD,[c] Donald E. Lewis,[a, b] Dorothy F. McCart, RN,[a, b] and Evelyn A. Mueller, RN[a, b]

Los Angeles and Pomona, California

An intrauterine probe electrode was inserted into 100 laboring women and 366 bipolar electrode combinations were tested. A noise-canceling technique was used with the final 28 subjects to remove competing maternal cardiac signals. Twenty-four (86%) had fetal heart rate tracings with sufficient technical quality to allow determination of the baseline fetal heart rate. (AM J OBSTET GYNECOL 1991;164:1233-4.)

Key words: Fetal electrocardiogram, fetal heart rate monitoring, intrauterine probe electrode

We developed a device to obtain the fetal electrocardiogram (ECG) for fetal heart rate (FHR) derivation without puncturing fetal skin.

Material and methods

One hundred women in labor at Los Angeles County/University of Southern California Women's Hospital in Los Angeles were selected for insertion of the device. The project was approved by our Institutional Review Board. All patients gave consent before insertion.

Each electrode consisted of 22-gauge, silver-silver chloride–plated, sterling silver wire wrapped along 0.25-inch segments of inert tubing used to measure intrauterine pressure. A 26-gauge copper wire connected each electrode to a standard fetal monitor leg plate. A varying number of electrodes was placed on each probe.

The technique for inserting the device was identical to that for intrauterine pressure catheter placement. The device was gently inserted to a depth of 12 to 18 inches. A fetal scalp electrode was also applied.

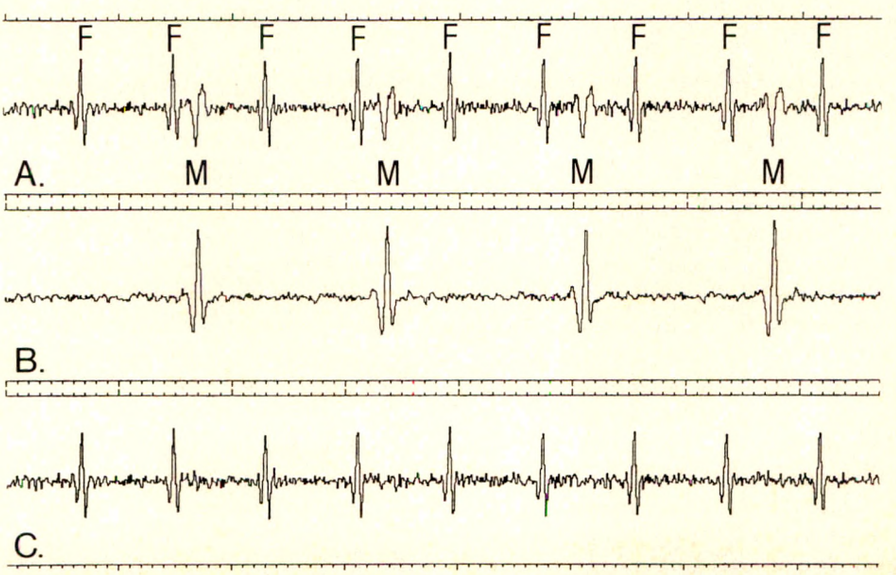

Fig. 1. Electronic processing of the probe-electrode signal. *A*, The probe-electrode signal. *B*, The maternal chest ECG. *C*, The processed signal after electronic elimination of signal *B* from signal *A*.

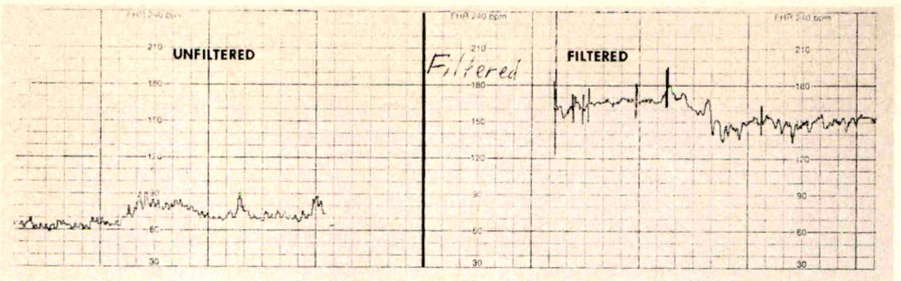

Fig. 2. The effect of electronic signal processing. Baseline heart rate switches from the maternal to the fetal rate.

The amplitude of the fetal QRS complex in microvolts was determined for both the fetal scalp electrode and probe device with a Hewlett-Packard 7826B single-channel ECG rhythm strip recorder. The ECG voltages obtained from the fetal scalp electrode and probe electrode were compared. Then the probe electrode was connected to a portable Corometrics 115 fetal monitor. The FHR tracings derived from the fetal scalp electrode were compared with those concomitantly obtained from the probe electrode.

To remove the competing maternal ECG from the signal, the final 28 devices used fetal ECG signal processing. An adaptive noise-canceling technique similar to that used by Widrow[1] transformed the maternal chest ECG signal to match the maternal ECG components found in the probe-electrode signal. The maternal chest ECG was then subtracted from the probe-electrode signal (Fig. 1). The processed tracings were considered improved if the device switched from a maternal baseline to a FHR baseline. If the probe electrode was tracking the FHR baseline before activating the signal processor, the "after" tracing was judged to be improved if the baseline FHR showed less artifact (Fig. 2).

Results

The mean fetal QRS complex voltage for all 366 bipolar electrode combinations tested was 40 μV and the mean fetal scalp electrode signal was 234 μV. The specific interelectrode distance of 9 inches (n = 92) produced the greatest mean fetal ECG voltage—66 μV (range, 10 to 875 μV). Electronic background noise noted during evaluation of the fetal R wave did not exceed 5 μV (peak to peak method; signal band width used, 15 to 40 cycles/sec).

When the 100 devices were connected to the fetal monitor, 46 produced FHR tracings. However, the majority of these FHR tracings had significant amounts of artifact. Among the final 28, the fetal tracing was improved in 20 (71%) with signal processing. However, among the eight not improved by the signal processor, four were already of good technical quality. Therefore the fetal probe electrode with signal processing had a success rate of 86% (24 of 28) in which the baseline FHR, variability, accelerations, and decelerations were discernible. When compared with tracings concomitantly obtained by fetal scalp electrodes, there was more artifact in the probe-electrode tracings.

Comment

Elimination of the competing maternal ECG enhances the ability to count the fetal ECG detected by the probe-electrode device. Additional electronic processing of the raw fetal ECG will likely further clean up the FHR tracing. However, a careful balance must be sought in this process. A visually pleasing FHR record may not mean that it is precise.

With a similar device, Randall et al.[2] achieved maximal fetal signals with an interelectrode interval of 7 inches. Therefore steric and electronic constraints suggest that the optimal electrode spacing for the device is 7 to 9 inches.

Randall et al.[2] argue that amniotic fluid attenuates the available signals. Therefore we propose that actual electrode contact with the fetal skin may be the critical factor for this type of fetal ECG signal detection.

We have developed and tested a device to detect fetal electrocardiac activity in labor that leaves the fetal skin intact. With further signal processing, this device may become clinically useful for continuous intrapartum FHR monitoring, especially if a single-probe device were equipped for simultaneous FHR and intrauterine pregnancy monitoring.

Management of radionecrosis of the vulva and distal vagina

William S. Roberts, MD,[a, c] Mitchel S. Hoffman, MD,[a, c] James P. LaPolla, MD,[a, c] Ernesto Ruas, MD,[b, d] James V. Fiorica, MD,[a, c] and Denis Cavanagh, MD[a, c]

Tampa, Florida

Twelve patients were seen between January 1983 and June 1989 with the clinical diagnosis of radionecrosis of the vulva or distal vagina. Seven patients received radiation for vulvar cancer, three for distal vaginal cancer, and two for recurrent endometrial cancer. No patient healed spontaneously and the mean delay in surgical therapy was 8.5 months. The radionecrotic site was treated with local therapy, radical local excision (with or without colostomy), or exenteration. The operative defect was closed primarily in three patients and covered with local flaps or myocutaneous flaps in seven patients. The two patients with local care still have radionecrotic ulcers. One of three patients who were closed primarily continues to have an ulcer. All other patients have healed satisfactorily except one who died after two attempts to correct the problem. Radionecrosis of the vulva and distal vagina should generally be treated surgically. (Am J Obstet Gynecol 1991;164:1235-8.)

Key words: Radionecrosis of the vulva

Delayed radiation injury is an unfortunate fact of life when curative doses of radiation therapy are given. The frequency and severity of these injuries are directly related to the total dose of radiation given to the affected area.[1] The exact mechanism of damage is unclear but the result is progressive fibrosis and loss of blood supply in the radiated tissue. This process may ultimately result in frank necrosis.

The skin was a frequent site of injury when orthovoltage radiation was in use. With the development of megavoltage radiation, injury to the skin has become much less common. Vulvar skin is notoriously less tolerant of radiation therapy than skin covering other areas of the body. Suggested reasons for this include moisture, friction, a nonflat surface, and a larger proportion of end arteries than that in other areas of skin. Despite this, radiation injury of the vulva occurs very infrequently.[2] In large part, this is because vulvar cancer is primarily treated surgically. When radionecrosis does involve the vulva or distal vagina, the typical patient is in severe pain and is hesitant to go out in public because of the foul odor. The patient is generally treated with narcotic analgesic agents, antibiotics, debridement, and intensive local care. A hyperbaric oxygen chamber may also be used if available.[3] Unfortunately, this intensive, conservative therapy is ineffective in most patients. We report our experience with the management of this rare clinical problem.

Material and methods

The charts of all patients with the clinical diagnosis of radionecrosis of the vulva or distal vagina managed by members of the Division of Gynecologic Oncology at the University of South Florida between Jan. 1, 1983, and June 1, 1989, were retrospectively reviewed. Any patient with obvious persistent or recurrent cancer within a necrotic tissue bed was excluded. A total of 12 patients were identified with a mean age of 68 years and a range of 34 to 85 years. Ten patients were white and two were black. The primary tumor site for which the patient received radiation and the International Federation of Gynecology and Obstetrics (FIGO) clinical stage are listed in Table I. All three patients with vaginal cancer had distal vaginal lesions, but both patients with recurrent endometrial cancer had vaginal apical lesions. The methods of radiation administration as well as accompanying or past therapies were extremely variable and are listed in Table II. Previous surgery was radical vulvectomy in two patients. Chemotherapy was concomitant intravenous cisplatin and 5-fluorouracil in one patient, intravenous bleomycin and 5-fluorouracil in one patient, and intraarterial cisplatin and floxuridine in one patient. The patient treated with surgery and external radiation had a wide local excision of the vulvar cancer. All external radiation was administered with a cobalt unit or linear accelerator. Vaginal brachytherapy was delivered with a Burnett cylinder. The maximum total dose of radiation to the radionecrotic site was estimated. The mean dose was 6699 cGy with a range of 4500 to 9400 cGy. Seven patients had some chronic medical conditions that may have contributed to a compromised blood supply in the radiated area and these are listed in Table III. Five patients had no identifiable predisposing conditions.

Table I. Site of cancer and stage

TOTAL	12

Table III. Associated medical conditions

Condition	*No. patients*
Essential hypertension	4
Noninsulin-dependent diabetes	3
Smoking	2
Previous stroke	1
Previous myocardial infarction	1
No predisposing conditions	5

Three patients had more than one condition.

The distribution of these chronic conditions in the study population is similar to that of the general elderly population. The mean time from completion of radiation to clinical evidence of necrosis was 16.2 months with a range of 3 to 69 months. All patients were initially treated with antibiotics, surgical debridement, and intensive local care including hydrogen peroxide, honey, and several other similar agents. One patient with a particularly large ulcer (Fig. 1) was treated intensively with hyperbaric oxygen.

Results

Conservative therapy did not result in even partial healing in any patient. Ten patients were ultimately treated with radical excision of the radionecrotic site. The two patients who were not treated surgically were elderly and not considered to be surgical candidates. Six of the 10 patients underwent radical excision of the radionecrotic site without removal of pelvic viscera. One of these patients had a colostomy because of the proximity of the ulcer to the anus and anal sphincter. This colostomy was later closed. Three patients required pelvic exenteration: one total, one anterior, and one posterior exenteration. One patient was initally treated with radical excision and colostomy but eventually required a total pelvic exenteration. Although it was not clinically suspected, three of the 10 patients had recurrent tumor in the excised specimens. Recurrent cancer developed later at the radionecrotic site in one patient not treated surgically. In the 10 patients treated surgically, the mean time from diagnosis of radionecrosis to surgical therapy was 8.5 months with a range of 2 to 20 months. Responsibility for this delay was shared by both ourselves and referring physicians.

The methods of tissue coverage after excision were variable and are seen in Table IV. The patient who underwent radical local excision before total pelvic exenteration had two separate attempts at coverage so the total in Table IV is 11 rather than 10. Of the 10 patients treated surgically, eight ultimately healed completely. One patient who had radical local excision with primary closure that failed continues to have a necrotic ulcer. Both coverage attempts failed in the patient who underwent radical local excision before pelvic exenteration and she ultimately died of surgery complications. Autopsy revealed no evidence of cancer. The coverage attempts in this particular patient were a unilateral gracilis myocutaneous flap that preceded local buttock flaps. Of the eight patients who healed completely, two had partial flap necrosis that resulted in introital stenosis. One of these patients underwent successful surgery to correct this problem. Three of these eight patients are sexually active. One of the two patients not treated surgically continues to have a radiation ulcer that is unchanged. The other patient died of cancer within the radiation ulcer. Of the 10 patients treated surgically, seven are alive without evidence of disease, two are dead of disease, and one died without evidence of disease as already mentioned. Recurrent problems have not developed in any patient who healed after surgical therapy.

Comment

Surgical treatment of radiation injuries of the skin has been advocated for many years.[1] This is classically composed of radical excision of all radiation-damaged tissue before appropriate tissue coverage. Whether this is widely practiced is unknown. Bloomer and Hellman[5] state, "These problems demand close cooperation between experienced surgeons and radiotherapists. Be-

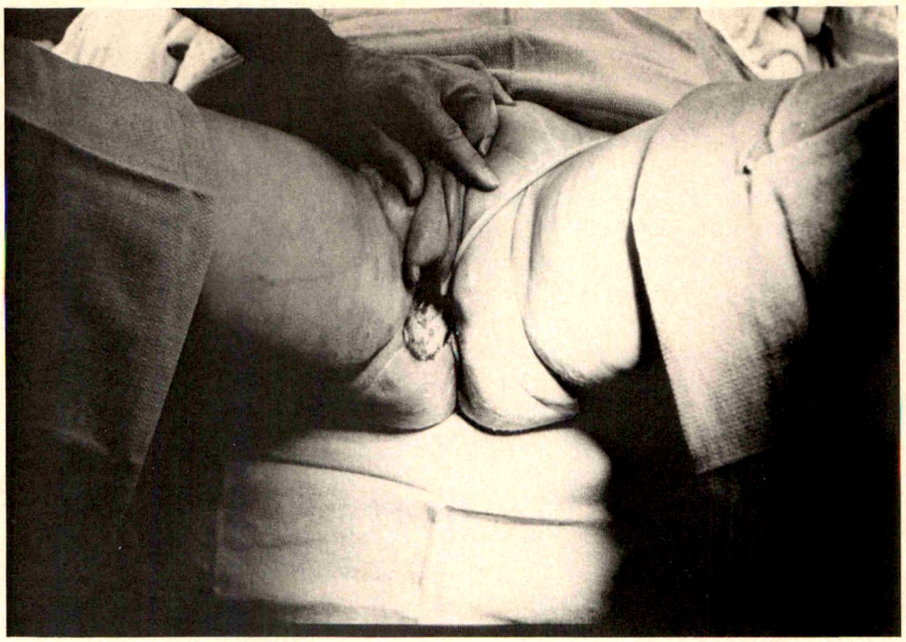

Fig. 1. Large radionecrotic ulcer of the vulva.

cause of the limited blood supply in the involved areas, conservative treatment is often all that is recommended." In our experience conservative therapy does not produce satisfactory results in the great majority of patients with radionecrosis of the vulva. Limited blood supply in the involved areas is precisely why conservative therapy does not result in complete healing.

Radionecrosis of the vulva is clearly a rare occurrence. Radiation to the vulva is seldom used in the primary therapy for carcinoma of the vulva. In the era of orthovoltage radiation necrosis developed in 30% of patients radiated for carcinoma of the vulva.[6] Megavoltage γ-radiation with or without interstitial therapy results in a 1.8% to 5% incidence of vulvar necrosis.[2, 7] With the use of electrons alone, Frischbier[8] reported a 4.5% incidence of radionecrosis of the vulva. In our experience interstitial radiation with or without external radiation carries a 60% risk of necrosis.[9] In recent years there has been increasing interest in radiation therapy combined with limited surgery in patients with advanced vulvar cancer.[10] The incidence of radionecrosis in these series was minimal but as interest in this approach increases the problem will likely become more common. There has also been interest in combining chemotherapy with radiation therapy in patients with advanced vulvar cancer.[11] Whether chemotherapy enhances the effect of radiation on normal vulvar skin remains to be seen. This approach may increase the incidence of radionecrosis of the vulva. Three patients in our series had chemotherapy combined with radiation therapy.

Table IV. Reconstruction after excision of radionecrotic site

Primary closure	3
Unilateral gracilis myocutaneous flap	3
Unilateral gracilis muscle flap covered with split-thickness skin graft	1
Bilateral gracilis myocutaneous flaps	2
Bilateral femoral fasciocutaneous flaps	1
Bilateral local buttock flaps	1
TOTAL	11

Late radiation damage is related to the total dose received, the dose rate, and the volume of the tissue radiated. In this series the total dose was variable and as little as 4500 rad was associated with necrosis. In two patients with recurrent endometrial cancer at the vaginal apex it was not intended to radiate the vulva at all. It can only be assumed that the Burnett cylinders were displaced in both patients. It is obvious that radionecrosis can occur even with relatively small doses of radiation.

In our experience conservative management did not result in healing in any patients with vulvar radionecrosis despite many months of trying. In our opinion if healing has not occurred in 1 to 2 months, surgery should be considered. With radical excision of all radiation-damaged tissue before appropriate tissue coverage, eight of 10 patients healed completely with good quality of life. Unfortunately, four of 10 patients required pelvic exenteration to remove all the radiation-damaged tissue. Two patients required a

colostomy and in our opinion one of these patients had preservation of the anus and fecal continence as a result of the temporary colostomy.

Tissue coverage was accomplished with primary closure in three patients. This resulted in complete healing in two patients. Primary closure requires a small defect with mobile surrounding tissues. Closure without tension is critical in this situation. Primary closure will not be appropriate in the majority of patients with this problem. Seven patients were closed with flaps, six of which were gracilis flaps. In one of these patients the gracilis muscle alone was used to fill the defect and was covered by a split-thickness skin graft. In this particular patient the gracilis myocutaneous flap was considered to be too bulky. The result was excellent. The gracilis muscle flap is very reliable and tends to be more reliable than the gracilis myocutaneous flap. It has been used successfully for other perineal defects.[12] Five of the six patients treated with gracilis myocutaneous flaps had complete healing. Others have had excellent success with gracilis myocutaneous flaps for radionecrosis of the vulva or distal vagina.[13-15] A total of six patients have been reported and all healed completely. The one patient in this series who did not heal had a huge defect and eventually required pelvic exenteration because of progressive necrosis. Two of the five patients with gracilis myocutaneous flaps that healed completely had some skin loss, which is common with gracilis myocutaneous flaps, and introital stenosis developed in both patients as a result of the skin loss.

Local full-thickness skin flaps have been used for radionecrosis of the vulva or perineum with reasonable success.[16, 17] In this series one patient had an excellent result with femoral fasciocutaneous flaps and local buttock flaps failed in one patient after failure of a gracilis myocutaneous flap. It is unlikely that these flaps are as reliable as the gracilis myocutaneous flaps. Nonetheless with good surgical judgment local flaps normally used for vulvar and perineal reconstruction after cancer surgery should be appropriate for coverage after radical excision of radionecrotic tissue.[18]

It is hoped that new local therapies will be developed that result in healing of these radionecrotic ulcers without surgery. Until then excision of all radiation-damaged tissue with appropriate tissue coverage will be the treatment of choice. It is possible that pelvic exenteration can be avoided by incomplete excision of the radiation-damaged tissue before coverage with myocutaneous flaps. The flap theoretically would accomplish biologic debridement. This has been advocated by Marino[19] with excellent results in terms of both healing and preservation of vital structures. We have no experience with this technique but it certainly deserves consideration. We did use hyperbaric oxygen in one patient without beneficial effect. It is possible that hyperbaric oxygen may help to heal smaller ulcers but we doubt its widespread use will significantly change the need for surgery for this problem.

Radionecrosis of the vulva or distal vagina is a difficult problem. Hesitation to subject the patient to extensive surgery is understandable. Unfortunately, delay in surgical treatment serves only to prolong the misery of the patient and may delay the diagnosis of recurrent cancer.

Cocaine and the use of alcohol and other drugs during pregnancy

Ann P. Streissguth, PhD,[a] Therese M. Grant, MEd,[a] Helen M. Barr, MS,[a] Zane A. Brown, MD,[b] Joan C. Martin, PhD,[a] Dennis E. Mayock, MD,[c] Sharon Landesman Ramey, PhD,[d] and Leejon Moore, MD[a]

Seattle, Washington, and Birmingham, Alabama

Recent reports of adverse pregnancy outcomes associated with prenatal cocaine exposure have raised questions about the actual numbers of infants who are exposed to cocaine in utero. Whereas toxicologic urine screens obtained at delivery can detect cocaine use in the preceding few days, they fail to yield a comprehensive picture of use during and immediately before pregnancy. According to postpartum self-report, 15% of a teaching hospital sample and 3% of a private hospital sample of mothers had used cocaine during pregnancy or in the previous month (total = 876). Rates at the teaching hospital reflect a fifteenfold increase over the past 12-year period, when compared with previously obtained data. Cocaine users were significantly more likely to report that they drank alcohol, smoked cigarettes, and took other illicit drugs during pregnancy than women who denied using cocaine. Mothers at highest risk for cocaine use were those who were black (20%), were single-separated-divorced (24% to 33%), and had less than a high school education (21%). (AM J OBSTET GYNECOL 1991;164:1239-43.)

Key words: Cocaine prevalence in pregnancy, alcohol prevalence in pregnancy

Recent reports have indicated an alarming increase in the use of cocaine. Cocaine use has been described by the director of the National Institute on Drug Abuse as a "major public health threat."[1] Cocaine readily crosses the placenta[2]; therefore effects on the fetus are of grave concern. Several recent studies have described perinatal effects of cocaine abuse, including intrauterine growth retardation,[3-7] earlier gestational age at delivery,[3, 4] and increased abruptio placentae,[3, 8, 9] as well as cerebral infarction, abnormal electroencephalogram, and neurobehavioral signs in the neonatal period.[3, 5, 6, 9-11] Intrauterine growth retardation was not significantly associated with prenatal cocaine exposure in one study,[12] and the findings of abruptio placentae were not replicated in two studies.[4, 11] It is possible that some of these discrepancies relate to the use of other drugs among cocaine-using women or to unique sample characteristics of the mothers studied.

This study was undertaken for three reasons: (1) to compare the prevalence of self-reported cocaine and other drug use among mothers at several Seattle area hospitals, (2) to examine the relationship of cocaine use to demographic characteristics and to the use of other drugs, and (3) to compare cocaine use during pregnancy in 1987 with similar data from 1975.

Material and methods

Cocaine use during pregnancy and in the month or so before pregnancy was assessed by self-report on a one-page Hospital Screening Questionnaire (HSQ) developed for this study after extensive pretesting. Similar information was obtained for other illicit drugs, alcohol, and tobacco. The hospital screening questionnaire, which begins with a statement about the purpose of the study and the confidentiality of the responses, was distributed in the postpartum unit on the first morning after delivery at three hospitals: a teaching hospital that includes a high-risk inner city population, as well as low-risk, more highly educated mothers, and two private hospitals, one urban and one suburban, serving more middle-class populations. Data from the latter two hospitals were combined because they were similar. All consenting mothers were given questionnaires by trained research assistants who identified themselves as separate from the hospital staff and who informed mothers that their responses would not be entered into their medical records. At the teaching hos-

pital the compliance rate was 88% for a total of 591 questionnaires obtained. At the private hospitals the compliance rate was 80% for a total of 285 completed questionnaires. The 1974 and 1975 comparison data from the teaching hospital were available on 405 mothers who had participated in a previous study,[13] in which the participation rate was 85% and the data were obtained by self-report during midpregnancy.

Results

For the 1987 data, the reported tobacco and illicit drug use differed markedly between the two types of hospitals (Table I), and except for some street drugs, more women reported use in the month before pregnancy than during pregnancy. However, because there are uncertainties regarding the timing of conception and recall across this 9-month period, we combined data from these two time periods in preparing the remaining tables. At the teaching hospital 15% of the mothers reported cocaine use during pregnancy or the previous month; at the private hospitals the comparable figure was 3%. Overall alcohol use was more comparable across hospitals, but teaching hospital mothers reported twice as much binge drinking as mothers from the private hospitals. Reported use of alcohol and other drugs declined significantly from the "month prior" to during pregnancy, except for the category of "other street drugs," which includes drugs such as heroin, PCP, and amphetamine but not marijuana and cocaine.

Table II shows that, as anticipated, the demographic characteristics of the mothers at the two hospitals are very different. Table III, which combines mothers from both hospitals, shows that maternal drug use is related to demographic variables. White mothers more frequently reported drinking during pregnancy, whereas black mothers more frequently reported use of tobacco and cocaine. Cocaine use is lowest among married and more highly educated mothers. The highest risk groups for drug use and binge drinking during pregnancy are high school dropouts and unmarried mothers. Table III also reveals the percentage of babies who were not exposed to drugs, according to maternal report of alcohol, cigarette, and/or illicit drug use, either in the month before pregnancy or during pregnancy. Only 26% of white babies and 34% of black babies were reportedly drug and alcohol free. Maternal marital status was related to drug- and alcohol-free babies: 35% of babies of married mothers, 17% of those of single mothers, and 11% of those of divorced-separated mothers were reportedly drug and alcohol free. Mothers who reported cocaine use were also more likely to report use of alcohol and other drugs than were cocaine abstainers (Table IV). We can see from Table IV that it is virtually impossible to study the effects of cocaine in the complete absence of other drugs, at least in this sample.

This study demonstrates that the dramatic increase in cocaine use in the general population over the past few years holds true for pregnant women as well. There was a fifteenfold increase in reported cocaine use at the teaching hospital during the 12-year period described (Table V). This change cannot be accounted for by demographic changes in the hospital population, as the teaching hospital population had relatively comparable demographics for the two time periods, except for a higher proportion of older and single mothers, a trend

Last column (labeled *None of these*) means no alcohol *and* no cigarettes *and* no marijuana *and* no cocaine *and* no other illegal "street" drugs.

that is ongoing at most obstetric centers.[14] Reported alcohol use decreased by 26% during pregnancy, whereas binge drinking (five or more drinks at a time) decreased to half of its 1975 level. The use of "other" illicit drugs (heroin, methadone, and amphetamines in about equal proportions) shows a fivefold increase over this 12-year period, while tobacco and marijuana use has remained relatively stable. Nevertheless, "any" alcohol (at 57%) and cigarettes (at 48%) were the two drugs most frequently reported as being used during pregnancy. We note that, although there were twice the percentage of women who reported no drug use in 1987 as compared with 1974, this still accounted for only 25% of the teaching hospital sample.

Comment

This study reveals that 15% of the women delivered of their infants at a teaching hospital reported using cocaine at some point during pregnancy or in the previous month. This represents a fifteenfold increase in cocaine use at this hospital over a 12-year period (see Fig. 1). Cocaine use was highest among women who were black, poorly educated, or single-divorced-separated. This is in contrast to recent data from the National Household

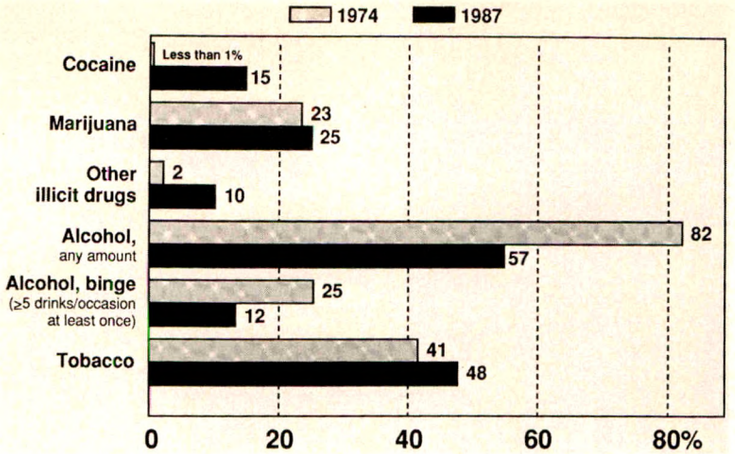

Fig. 1. This figure shows changes in self-reported use of cocaine, alcohol, and other drugs for 1975 versus 1987 at teaching hospital only. Data here combine two time periods during pregnancy and just before pregnancy or pregnancy recognition. *Other illicit drugs* includes heroin, methadone, amphetamines, and all other illicit drugs except cocaine and marijuana.

Table IV. Use of drugs by cocaine users versus abstainers (N = 876)

Two of the 876 patients provided no information on cocaine. The denominators in these columns are smaller than indicated by number of identified cocaine users or abstainers because some questions were not asked on the first editions of these pilot study questionnaires or some patients did not provide answers for all information requested.

Drug Survey,[15] which found a 3.5% rate of cocaine use "during the past month" among black and white women of childbearing age who were not pregnant. The prevalence figures from the teaching hospital do not generalize well to the private hospitals, which may be due in part to demographic differences in the patient populations. Approximately 3% of the mothers at private hospitals reported cocaine use during pregnancy.

Alcohol use has decreased significantly over the past 12 years in our study; however, a recent report from Texas cites a twofold increase in alcohol abuse (defined as ≥2 ounces of absolute alcohol per day, on average) between 1977 to 1980 and 1987.[16] In our 1987 study the highest use was among white mothers, and the highest binge drinking rate was among white mothers and teenagers. In contrast to the demographics associated with cocaine use, binge drinking was reported more frequently among mothers without a high school education and those with some college (Table III). This pattern of reported use of five or more drinks per occasion has recently been associated with significantly lower IQ scores and more learning problems in exposed 7-year-old children.[17]

Mothers who reported using cocaine during pregnancy also were more likely to use alcohol and other drugs. This suggests that for studies of cocaine teratogenesis, assessment of other drug exposures must be carefully integrated into the study design. This is particularly true for marijuana, which was used by 68% of the cocaine users but only 14% of the cocaine abstainers, and binge alcohol, which is the drinking pattern for 30% of the cocaine users but only 8% of the cocaine abstainers.

The widespread increase in reported cocaine use

during pregnancy or in the previous month demonstrated in this study, as well as the frequent combination of cocaine with alcohol and other drugs of abuse, indicates that a large number of infants are born drug exposed. At the teaching hospital 75% of the babies were apparently exposed to alcohol, tobacco, and/or illicit drugs; 32% were exposed to illicit drugs alone (Table I).

The long-term consequences associated with prenatal alcohol use are well documented,[18] but little is known about the ultimate effects of prenatal cocaine exposure, although warnings about short-term effects have been issued.[19] An unpublished pilot study from our unit indicates some developmental delay and considerable social upheaval in the lives of babies exposed to cocaine in utero; only 45% of the babies born to cocaine-using mothers were still in the care of their biologic mothers at 6½ months of age. However, identification of cocaine as a correlate of infant outcomes independent of other covariates was not possible because of confounding with social factors, reported exposure to other drugs, and small sample size. It is essential that long-term follow-up studies be undertaken to examine the neurobehavioral consequences of prenatal cocaine exposure. Recent research from animal laboratories suggests that prenatal cocaine exposure does alter central nervous system development.[20, 21]

This study indicates that hospital screening of postpartum women is a useful method of potentially identifying infants exposed prenatally to alcohol, tobacco, and illegal drugs. Drug testing of all mothers during pregnancy may not be feasible and urine screening of all newborns can be fraught with medical-legal problems; therefore this questionnaire approach provides a reasonable alternative to identify high-risk mothers and babies at delivery. This self-report questionnaire could be adapted effectively for pregnant women as well. Knowledge about prenatal alcohol and drug exposure is an essential step in prevention and intervention efforts.

We gratefully acknowledge the contributions of Cara C. Ernst, Pam Phipps, Katherine Scott, Teree Gilbert, and Pamela Swanborn for technical assistance, and the cooperation of the Obstetrical and Nursing Services at University of Washington Medical Center, Northwest Hospital, and Overlake Hospital.

Fetal thyroid-stimulating hormone response to maternal administration of thyrotropin-releasing hormone

J.G. Thorpe-Beeston, MD,[a] K.H. Nicolaides, MD,[a] R.J.M. Snijders, MSc,[b] J. Butler, MA,[b] and A.M. McGregor, MD[c]

London, England

Thyroid-stimulating hormone was measured in fetal blood samples obtained by cordocentesis before and after blood transfusion in Rh-affected pregnancies at 25 to 37 weeks' gestation. In eight of 26 study subjects thyrotropin-releasing hormone was given to the mothers immediately after the pretransfusion samples were obtained. In this group the fetal thyroid-stimulating hormone concentrations in the posttransfusion samples were significantly higher than those before the transfusion. (AM J OBSTET GYNECOL 1991;164:1244-5.)

Key words: Thyroid function, cordocentesis, respiratory distress syndrome

Animal studies have shown improvement in fetal pulmonary maturation after the maternal administration of thyrotropin-releasing hormone.[1] In human beings, intravenous injection of thyrotropin-releasing hormone to pregnant women within 3 hours before delivery at term was associated with increased thyroid-stimulating hormone concentrations in cord blood at delivery.[2, 3] The aim of this study was to investigate whether maternal thyrotropin-releasing hormone, administered at earlier gestations, could also stimulate the fetal pituitary.

Patients and methods

Serum thyroid-stimulating hormone was measured by radioimmunoassay in maternal and umbilical venous blood samples[4] obtained immediately before and after fetal blood transfusion by cordocentesis,[5] in 26 red blood cell isoimmunized pregnancies at 25 to 37 weeks' gestation. In eight patients, immediately after obtaining the pretransfusion fetal blood sample, thyrotropin-releasing hormone (200 μg) was given intravenously to the mothers.

Results

In the eight patients who were given thyrotropin-releasing hormone, gestation (mean = 32, SD = 2 weeks), fetal hemoglobin increase as a result of the transfusion (mean = 6.5, SD = 1.2 gm/dl), expansion of the fetoplacental blood volume[5] (mean = 70, SD = 24%), and rate of transfusion (mean = 8.7, SD = 2.9 ml/min) were not significantly different from the corresponding values in the 18 patients who were not given thyrotropin-releasing hormone (mean = 30, SD = 3 weeks, $t = -1.87$; mean = 6.6, SD = 2.4 gm/dl, $t = -0.03$; mean = 97, SD = 63%, $t = 1.12$; mean = 10.8, SD = 3.9 ml/min, $t = 2.28$, respectively).

In the group that received thyrotropin-releasing hormone, the mean thyroid-stimulating hormone concentration in the posttransfusion samples was significantly higher than that before the transfusion both in maternal (Fig.1; mean difference = 7.687 mU/L, $t = 6.04$, $p < 0.001$) and fetal blood (Fig. 1; mean difference = 41.929 mU/L, $t = 6.27$, $p < 0.01$). The percentage increase in fetal thyroid-stimulating hormone concentration was significantly related to the time interval between the administration of thyrotropin-releasing hormone and the collection of the posttransfusion samples (Fig. 1; $r = 0.832$, $n = 8$, $p < 0.05$), but not to gestation at transfusion ($r = 0.092$), the change in fetal hemoglobin concentration ($r = 0.03$), the rate of transfusion ($r = 0.228$), or expansion of the fetoplacental blood volume ($r = 0.427$). In the control group there were no significant differences between the pretransfusion and posttransfusion thyroid-stimulating hormone concentrations in either the fetal (mean difference = 1.317, $t = 1.03$) or maternal blood (mean differences = 0.13, $t = 1.11$).

Comment

Fetal blood transfusion does not change the fetal thyroid-stimulating hormone concentration. However, maternal administration of thyrotropin-releasing hormone is associated with a rapid increase in fetal thyroid-stimulating hormone. Because the magnitude of the

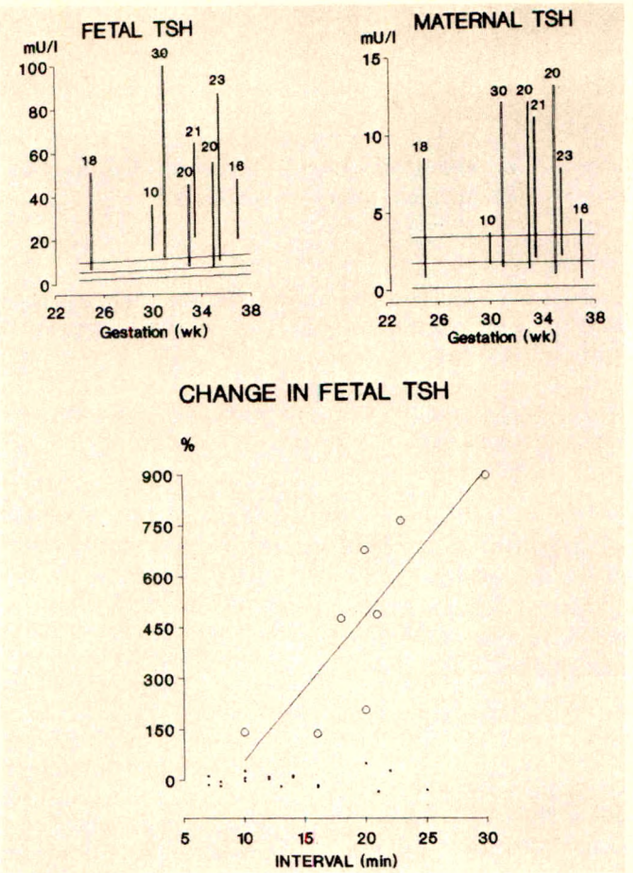

Fig. 1. Increase in fetal and maternal blood concentration of thyroid-stimulating hormone (mU/L) within 10 to 30 minutes from administration of thyrotropin-releasing hormone (actual time interval given above thyroid-stimulating hormone response in each case), plotted on appropriate reference range (mean, 5th, and 95th percentiles) for gestation *(top)*. Change in fetal thyroid-stimulating hormone is significantly related to time interval from administration of thyrotropin-releasing hormone to mother (o); in control fetuses (.) there was no significant difference between pretransfusion and posttransfusion thyroid-stimulating hormone concentrations.

fetal response is similar to that reported in fetuses undergoing thyrotropin-releasing hormone stimulation at term,[2, 3] the data of the present study suggest that fetal pituitary responsiveness is established from at least 25 weeks' gestation. Furthermore, the fetal response to thyrotropin-releasing hormone is much greater than the maternal response, and this increased sensitivity may be a consequence of reduced negative feedback on the pituitary because the fetal thyroid hormone concentration is lower than that in postnatal life.[4]

Further study is necessary to investigate the reproducibility of these findings in normal pregnancies and to define the possible effect of the increased fetal thyroid-stimulating hormone on the fetal thyroid gland, the time course of this response, and whether maternal thyrotropin-releasing hormone, unlike corticosteroids, can enhance fetal lung maturation from as early as 25 weeks' gestation.

In utero diagnosis and management of fetal subdural hematoma

Siegfried Rotmensch, MD, Peter A. Grannum, MD, José A. Nores, MD, Cynthia Hall, MD, Marc S. Keller, MD, Shirley McCarthy, MD, and John C. Hobbins, MD

New Haven, Connecticut

The in utero ultrasonographic diagnosis of a fetal subdural hematoma is presented. The value of percutaneous umbilical blood sampling, transvaginal ultrasonography, and magnetic resonance imaging for diagnosis and management is discussed. (AM J OBSTET GYNECOL 1991;164:1246-8.)

Key words: Subdural hematoma, percutaneous umbilical blood sampling, transvaginal ultrasonography, magnetic resonance imaging

The in utero diagnosis of subdural hematoma has been reported in two cases.[1, 2] Percutaneous umbilical blood sampling, transvaginal ultrasonography, and magnetic resonance imaging have added new dimensions to the identification and management of this entity. We report a case and suggest guidelines for management.

Case history

A 37-year-old Haitian woman, gravida 4, para 3, was first seen at 32 weeks' gestation. Physical examination revealed a uterine fundal height of 37 cm. A transabdominal ultrasonographic scan showed a single live fetus in vertex presentation with moderate polyhydramnios. Biometry of the long bones was consistent with 32 weeks' gestation. Gross fetal anatomy appeared normal except for the intracranium, which could not be well visualized because of engagement of the fetal head in the pelvis. The biparietal diameter was consistent with a gestation of 37 weeks 5 days.

A transvaginal scan showed a grossly abnormal intracranial anatomy (Fig. 1). The brain was displaced from the inner table of the cranium by a hypoechoic extraaxial fluid collection. Within this extraaxial fluid, two hyperechoic irregular masses were seen in the right frontoparietal area. The right hemisphere and falx were displaced toward the left. The ventricular system was not dilated, and there was no evidence of intraventricular hemorrhage. The frontal portion of the lateral ventricles and the hippocampal gyri appeared to be symmetrically compressed by the extraaxial fluid. Interestingly, the sulci of the brain tissue were markedly accentuated and appeared as bright echogenic lines. The central areas of the brain tissue, which correlated with the anatomic location of white matter, appeared significantly more echogenic in comparison with the peripheral brain tissue, raising suspicion of evolving infarction or encephalomalacia. The cerebellar vermis and hemispheres could not be clearly outlined and appeared as an irregularly shaped mass in the posterior fossa.

The above findings were suggestive of a fetal subdural hematoma with multiple blood clots in the subdural space and secondary compression of brain tissue.

Percutaneous umbilical blood sampling was performed for chromosome analysis, fetal acid-base status, and coagulation profile. The following results were obtained: pH, 7.35; base deficit, −8.2 mmol/L; hematocrit, 14.1%, prothrombin time, 64.6 seconds (control, 11.1 seconds); partial thromboplastin time, >2 minutes (control, 28.6 seconds), platelet count, 236,000/ml; and a weakly positive direct Coomb's test. Fetal liver function tests and plasma protein level were within normal limits. The mother's blood type was O negative with an anti-D titer of 1:64. Screening tests for cytomegalovirus and toxoplasmosis were negative.

An intrauterine transfusion of 130 ml of O-negative packed red blood cells was performed, which raised fetal hematocrit to 30%. Because of the unexplained fetal coagulopathy, 30 ml of fresh frozen plasma was transfused empirically. After the transfusion the nonstress test became reactive for the first time, and the biophysical profile scored 10 points on a scale of 10. Amniocentesis revealed mature lung indices. The fetal karyotype was normal 46,XY.

To further characterize the intracranial findings, a magnetic resonance imaging scan of the fetal brain was obtained, which confirmed the diagnosis (Fig. 2). Fetal paralysis during the scan was achieved with pancuronium bromide, 0.1 mg/kg, via cordocentesis.

In consultation with the neonatologists, delivery was delayed despite mature fetal lung indices, to reduce the potential for other complications of prematurity. Nine days after the intrauterine transfusion, the daily nonstress test became nonreactive again, and the biophys-

ical profile failed to reveal breathing movements and tone. Marked polyhydramnios had acutely formed. An emergency low-transverse cesarean section was performed, and a male fetus weighing 2890 gm with Apgar scores of 3 and 5 at 1 and 5 minutes, respectively, was delivered. The umbilical cord arterial pH was 7.19 with a base deficit of −8.0 mmol/L. Marked craniomegaly with widespread sutures and bulging fontanelles were noted. The immediate neonatal course was complicated by multiple episodes of bradycardia. Respiratory efforts were essentially absent, leading to intubation. Neonatal brain scans by both ultrasonography and computed tomography revealed a large subdural hematoma, diffuse cerebral edema, and massive bilateral intraventricular and periventricular hemorrhages. The infant died 6 hours after delivery. Autopsy confirmed the diagnosis of bilateral subdural hematomas with multiple organized clots in the subdural space and massive intraventricular hemorrhage.

Comment

The antenatal diagnosis of a subdural hematoma can be based on the findings described. Transvaginal ultrasonography was of great value in complete visualization of the cranium in this fetus with vertex presentation, and magnetic resonance imaging was a useful adjunct for confirmation. Fetal paralysis with pancuronium via cordocentesis allowed for diagnostic magnetic resonance imaging without interference by fetal motion. We believe that the enhanced echogenicity of sulci and the apparent differential echogenicity of white and gray matter in our case reflect brain edema. Furthermore, the rim of fluid surrounding the brain in the subdural space might have provided an additional acoustic window, resulting in accentuation of the brain texture.

The prognosis for a fetus affected by subdural hematoma is conceivably dependent on the severity of the hemorrhage and the underlying cause. In one of the previously reported cases hypotonic quadriparesis and bilateral optic atrophy subsequently developed in the surviving infant.[2] In another case the fetus survived but experienced neonatal seizures.[1] The prognosis thus far appears to be dismal.

Our experience with fetal hydrocephalus has taught us that brain function cannot be predicted accurately by ultrasonographic findings except in the most severe cases. In the absence of extensive experience with fetal subdural hematoma, it appears prudent to optimize antenatal treatment and delivery management in the expectation of fetal survival. In contrast to the management of our own case, we suggest delivery as soon as fetal lung maturity is determined. In this case fetal intraventricular hemorrhage must have occurred in the 24-hour period before delivery or immediately post partum, since daily ultrasonographic scans showed no evidence of this complication. Earlier delivery might have prevented the occurrence of intraventricular hemorrhage.

If indicators of lung maturity are negative, we suggest percutaneous umbilical blood sampling for diagnosis and possible intrauterine transfusion. Percutaneous umbilical blood sampling revealed a severe co-

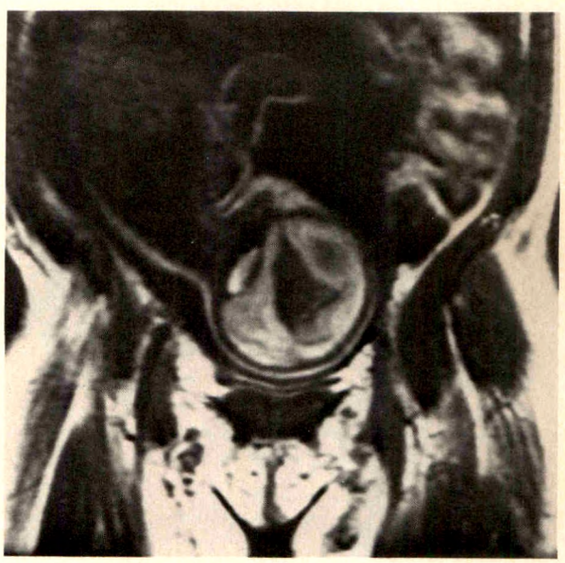

Fig. 2. T1-weighted (repetition time 500 msec; echo time 20 msec) magnetic resonance imaging in the coronal plane of mother but in sagittal plane of fetal head. In this sequence brightest signals are obtained from blood and fat. Fetal subdural hematoma surrounds the brain, whereas subcutaneous fat outlines external surface of fetus.

agulopathy and anemia in this case. Both were partially corrected by transfusion of donor blood cells and fresh-frozen plasma. Even though postransfusion clotting function could not be obtained, the coagulation function and hematocrit were improved 9 days later, at the time of delivery. Fetal blood specimens were not sufficient for a complete hematologic evaluation.

The route of delivery was by cesarean section in all three reported cases, because of remarkable enlargement of the head size. Undoubtedly, the overall efforts and maternal risks might appear excessive, considering the dismal outcome in at least two of the three cases which have so far been reported. However, physicians are ethically committed to optimize treatment in cases of a central nervous system lesion with yet undetermined outcome.[3]

Calcium-regulating hormones and osteocalcin levels during pregnancy: A longitudinal study

Katsuyoshi Seki, MD, Noriko Makimura, DMSc, Chieko Mitsui, BS, Junko Hirata, BS, and Ichiro Nagata, MD

Tokorozawa City, Saitama, Japan

We measured serum concentrations of calcium-regulating hormones and osteocalcin in 20 women longitudinally throughout pregnancy. 1,25-Dihydroxyvitamin D levels were high early in pregnancy and increased with advancing gestation. Parathyroid hormone and osteocalcin levels were low in early pregnancy. They declined toward the middle of pregnancy, but increased in late pregnancy. The serum osteocalcin level correlated with the parathyroid hormone level. The synthesis of osteocalcin by osteoblasts is stimulated by the action of 1,25-dihydroxyvitamin D, and serum osteocalcin levels are also related to the levels of parathyroid hormone. During early and mid pregnancy, the stimulatory effect of 1,25-dihydroxyvitamin D on the synthesis of osteocalcin may be overridden by the inhibitory effect of declining parathyroid hormone levels. The increase in osteocalcin level in late pregnancy may be a consequence of increasing levels of both parathyroid hormone and 1,25-dihydroxyvitamin D. (Am J Obstet Gynecol 1991;164:1248-52.)

Key words: Calcium-regulating hormone, osteocalcin, pregnancy

The effect of pregnancy on the maternal calcium content is unclear.[1] The issue has been investigated by means of photon absorptiometry or x-ray spectrophotometry, but the results appear contradictory. Osteocalcin is a bone-specific protein released into the circulation proportional to the rate of new bone formation.[2] The usefulness of serum osteocalcin measurements as a clinical marker of bone turnover is becoming more widely accepted.[3, 4] Serum osteocalcin levels are lower in pregnant women compared with nonpregnant women, indicating reduced bone turnover during pregnancy.[5] However, the cause of the decrease in osteocalcin levels during pregnancy is unclear. The synthesis of osteocalcin by osteoblasts is stimulated by the action of 1,25-dihydroxyvitamin D [$1,25(OH)_2D$],[6] and serum osteocalcin levels also are influenced by parathyroid hormone.[3] Serum $1,25(OH)_2D$ is increased early in pregnancy and continues to rise until delivery.[7]

6/1/27004

The relationship between serum osteocalcin and parathyroid hormone has been studied by two groups of investigators. In women during midpregnancy, serum osteocalcin levels were low in both reports, whereas serum parathyroid hormone levels were high in one[5] and were not significantly different in the other, when compared with nonpregnant women.[8] These findings suggest that factors other than parathyroid hormone or $1,25(OH)_2D$ are likely to be responsible for the decreased osteocalcin level during pregnancy.

However, there are also reports that indicate that parathyroid hormone levels in pregnant women may be lower than those in nonpregnant women and that serum intact parathyroid hormone may decline during pregnancy.[9, 10] If this is the case, low serum osteocalcin levels during pregnancy may be related to the decreased parathyroid hormone secretion. Serum osteocalcin and intact parathyroid hormone levels have not heretofore been measured in the same pregnant women. To further evaluate the changes in serum osteocalcin during pregnancy and to identify possible causes of the changes in osteocalcin levels, we measured blood levels of calcium, phosphorus, calcium-regulating hormones, and osteocalcin longitudinally throughout pregnancy.

Material and methods

The study population consisted of 20 women, ranging in age from 22 to 34 years. Twelve were nulliparous and eight were multiparous. All patients experienced uncomplicated pregnancies of duration between 38 and 41 weeks from the onset of the last menstruation. They received no medication except ferrous sulfate. Nineteen were delivered vaginally after normal labor, and one was delivered by cesarean section because of dysfunctional labor. All infants were normal at birth and weighed between 2.79 and 3.56 kg. All women breast-fed their infants through at least the first 6 weeks post partum.

Blood samples were collected by antecubital venipuncture in the morning, after an overnight fast. The initial samples were obtained on entry into the study before completion of 7 weeks from the onset of the last menstruation, and subsequent samples were collected at 4-week intervals throughout the remainder of gestation, on the third postpartum day, and during the sixth postpartum week.

Serum calcium levels were determined by atomic absorption spectrophotometry (model 603, Perkin-Elmer, Norwalk, Conn.) and phosphorus levels, by the Fiske and SubbaRow colorimetric procedure. Ionic calcium (Ca^{++}) activity was measured in a serum aliquot handled anaerobically with a NOVA 8 calcium analyzer (NOVA Biomedical, Waltham, Mass.).

Serum intact parathyroid hormone was determined with the commercially available immunoradiometric assay (Allegro-Nichols Institute, San Juan Capistrano, Calif.). This system is a two-site immunoradiometric assay, with two different, affinity-purified goat polyclonal antisera to human parathyroid hormone, one binding with the midregion and C-terminal portion of parathyroid hormone and a second binding with the N-terminal region; the latter is radiolabeled with iodine 125. The sensitivity of the assay was 1 pg/ml, and it is believed to accurately quantify the intact form of parathyroid hormone, PTH-(1-84).[11]

Serum calcitonin was measured by radioimmunoassay with kits obtained from Daiichi Radioisotope Laboratory (Tokyo), and serum osteocalcin was quantitated by radioimmunoassay with kits obtained from the Commissariat a l'Energie Atomique (Gif-sur-Yvette, France). The intraassay and interassay coefficients of variation were $<10\%$ in the assays for intact parathyroid hormone, calcitonin, and osteocalcin.

$1,25(OH)_2D$ was measured by radioreceptor assay after extraction and purification of the samples by column chromatography. The radioreceptor assay was performed as described by Eisman et al.[12] The sensitivity of the assay was 9 pg/ml, and the intraassay and interassay coefficients of variation were $<5\%$, respectively.

Statistical analyses were performed with analysis of variance, and regression analysis was done with repeated measures.

Results

Mean ($\pm$SD) levels of calcium, Ca^{++}, phosphorus, parathyroid hormone, calcitonin, $1,25(OH)_2D$, and osteocalcin during pregnancy and the puerperium are shown in Fig. 1. Calcium levels for weeks 20 to 23 through week ≥ 36 of pregnancy were significantly lower than those 6 weeks post partum, whereas those of week ≤ 7 through weeks 16 to 19 of pregnancy were not. The first-degree regression of mean calcium levels on duration of pregnancy was significant ($F = 65.6$, $p < 0.005$) (Fig. 1). Calcium levels 3 days post partum were significantly lower than those 6 weeks post partum.

Ca^{++} levels were not significantly different from those 6 weeks post partum throughout pregnancy (Fig. 1). Ca^{++} exhibited relatively little fluctuation during pregnancy, and neither first-degree ($F = 4.5$, not significant) nor second-degree ($F = 0.27$, not significant) regression provided a satisfactory fit. Ca^{++} levels were not significantly different between 3 days and 6 weeks post partum.

For weeks 28 to 31 through week ≥ 36 but not week ≤ 7 through weeks 24 to 27, the p levels were significantly lower than those 6 weeks post partum (Fig. 1). The p levels declined progressively throughout preg-

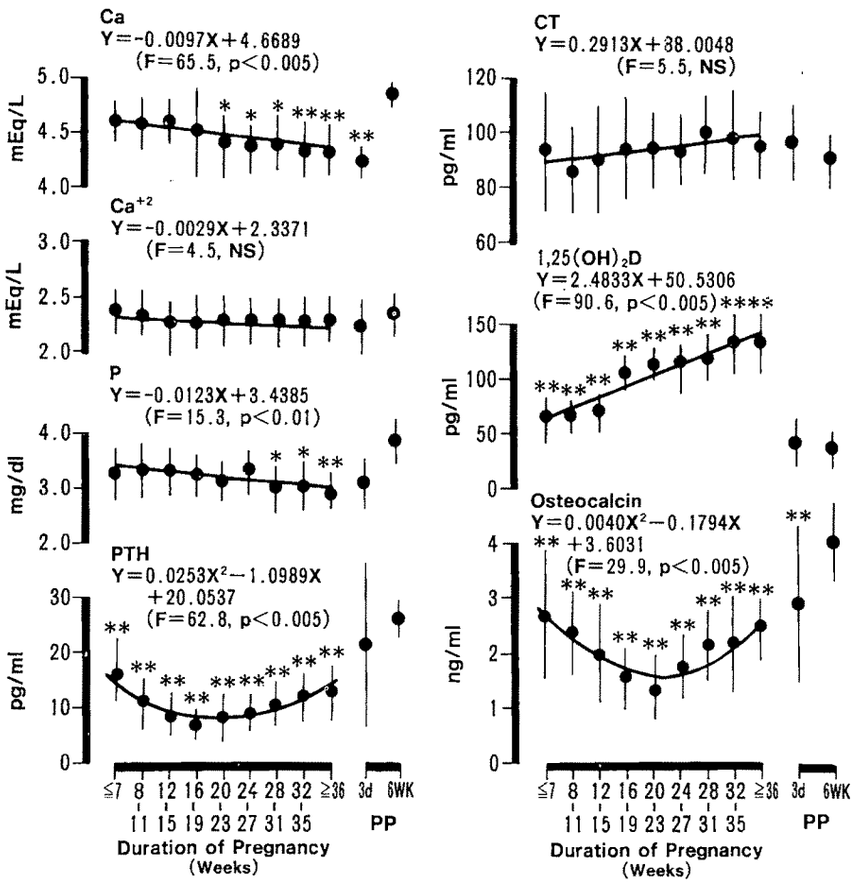

Fig. 1. Mean (±SD) levels of calcium *(Ca)*, Ca^{++} *(Ca^{+2})*, phosphorus *(P)*, parathyroid hormone *(PTH)*, calcitonin *(CT)*, $1,25(OH)_2D$, and osteocalcin during pregnancy and the puerperium *(PP)* and their regressions on duration of pregnancy (first degree: calcium, Ca^{++}, phosphorus, calcitonin, and $1,25(OH)_2D$; second degree: parathyroid hormone and osteocalcin). *Asterisk*, $p < 0.05$; *double asterisk*, $p < 0.01$ compared with 6 weeks post partum.

nancy, and the first-degree regression was significant ($F = 15.3$, $p < 0.01$). The p levels for 3 days post partum were not significantly different from those for 6 weeks post partum.

Parathyroid hormone levels were significantly lower than those 6 weeks post partum throughout pregnancy (Fig. 1). Levels declined toward the middle of pregnancy and increased thereafter. Although the first-degree regression was not significant ($F = 0.01$, not significant), a second-degree regression provided a satisfactory fit ($F = 62.8$, $p < 0.005$). Parathyroid hormone levels were not significantly different between 3 days and 6 weeks post partum.

Calcitonin levels were not significantly different compared with those 6 weeks post partum throughout pregnancy, and the first-degree regression was not significant ($F = 5.5$) (Fig. 1). Calcitonin levels on the third postpartum day were not significantly different from those 6 weeks post partum.

$1,25(OH)_2D$ levels were significantly higher than those 6 weeks post partum throughout pregnancy (Fig. 1). $1,25(OH)_2D$ levels increased during pregnancy, and the first-degree regression was highly significant ($F = 90.6$, $p < 0.005$). $1,25(OH)_2D$ levels for 3 weeks post partum were not significantly different from those for 6 weeks post partum.

Serum osteocalcin levels were significantly lower than those 6 weeks post partum throughout pregnancy (Fig. 1). Serum osteocalcin levels declined toward the middle of pregnancy and increased subsequently. Although the first-degree regression was not significant ($F = 0.15$), the second-degree regression was significant ($F = 29.9$, $p < 0.005$). Serum osteocalcin levels 3 days post partum were significantly lower than those 6 weeks post partum.

Osteocalcin levels correlated significantly with parathyroid hormone levels in 17 of the 20 women (correlation coefficients: 0.82, 0.88, 0.73, 0.68, 0.67, 0.91,

0.87, 0.86, 0.79, 0.75, 0.69, 0.77, 0.67, 0.67, 0.86, 0.90, 0.89) but not in the other 3 women (correlation coefficients: 0.57, 0.64, 0.61). Furthermore, mean osteocalcin levels correlated with mean parathyroid hormone levels during pregnancy (correlation coefficient, 0.91; $p < 0.005$).

Comment

Calcium and phosphorus in maternal serum declined during pregnancy. This is in keeping with the results of other reported studies.[1] Serum levels of Ca^{++} showed no significant change during pregnancy. Previous studies on Ca^{++} levels during pregnancy yielded contradictory results, with increasing and decreasing trends noted in different reports, both cross-sectional investigations with flow-through electrode analysis.[1] According to the longitudinal investigation of Pitkin et al.,[13] Ca^{++} values declined only slightly during pregnancy. Therefore the effect of pregnancy on serum Ca^{++} levels, if any, is considered minimal.

Most studies of parathyroid hormone, with traditional radioimmunoassays, have yielded results that support the concept of a physiologic hyperparathyroidism.[1] However, other investigators were unable to document a rise in serum parathyroid hormone in pregnancy, and a few reported that the levels may, in fact, be lower than those in nonpregnant women.[1, 10] These discrepancies arise, at least in part, from the limitations of traditional radioimmunoassays. Because of the presence of multiple species of predominantly inactive parathyroid hormone fragments, there is a marked discrepancy between total circulating levels of parathyroid hormone immunoactivity and bioactivity. Recently, Davis et al.[10] assessed the effect of pregnancy on parathyroid function using immunoradiometric assay for intact parathyroid hormone. They found a lower serum intact parathyroid hormone concentration in pregnant women compared with nonpregnant women, with lower values apparently as early as the first trimester. Although the results of our study are in general agreement with those of Davis et al., there are some discrepancies. They reported that the mean parathyroid hormone levels in the different trimesters were similar. In this study the levels declined toward the middle of pregnancy and increased thereafter. These discrepancies may be ascribed to the different investigational methods (cross-sectional vs longitudinal studies).

Previous studies on calcitonin secretion during pregnancy yielded inconsistent results.[1] We found no discernible change in calcitonin levels during pregnancy. This is in keeping with the data from a longitudinal study of Pitkin et al.,[13] in which no significant change in calcitonin levels was found. Thus the effect of pregnancy on calcitonin secretion, if any, may be minimal.

In agreement with the results of other reported studies,[1, 14, 15] $1,25(OH)_2D$ levels were high early in pregnancy and increased with advancing gestation. The principal physiologic factor promoting renal hydroxylation of 25(OH)D is parathyroid hormone. However, parathyroid hormone is not likely to be the cause of increased $1,25(OH)_2D$ formation, since parathyroid hormone levels were low during pregnancy. Therefore other factors may be responsible for the increased $1,25(OH)_2D$ level. In animals, some maternal serum $1,25(OH)_2D$ may be derived from the placenta. A capacity for 1α-hydroxylation of 25(OH)D has been demonstrated in the nephrectomized pregnant rat in vivo and in rat placenta and human decidua in vitro.[16-18] Breslau and Zerwekh[19] have demonstrated patients with pseudohypoparathyroidism who, while previously requiring vitamin D therapy to compensate for the impaired renal capacity to synthesize $1,25(OH)_2D$ were able to maintain normal serum $1,25(OH)_2D$ and calcium levels during pregnancy with no such treatment. The pregnancy-induced increase in circulating $1,25(OH)_2D$ may be the primary mediator of changes in maternal calcium metabolism.[9] Thus the increased $1,25(OH)_2D$ level may be the cause of decreased parathyroid hormone secretion during pregnancy.

It has been argued that the rise in $1,25(OH)_2D$ levels seen in early pregnancy is largely an artifact of an increase in the circulating concentration of the vitamin D-binding protein and that the free $1,25(OH)_2D$ index is not increased until late pregnancy.[15] However, Gertner et al.[9] demonstrated that pregnant women have physiologic absorptive hypercalciuria similar to that in patients with nephrolithiasis who have elevated serum $1,25(OH)_2D$ levels or in normal subjects given exogenous $1,25(OH)_2D$. It is not entirely clear whether pregnancy is accompanied by an increase in both bound and free $1,25(OH)_2D$.

Serum osteocalcin levels were low during pregnancy and lowest during midpregnancy. The findings are in general agreement with the results of other reported studies,[5, 8] and are compatible with a sequence in which bone turnover is reduced during early pregnancy, further decreases toward the middle of pregnancy, and increases in late pregnancy to the level of early pregnancy. The serum osteocalcin correlated with the parathyroid hormone level. This is in contrast to the results of Cole et al.,[5] who found no significant correlation between osteocalcin and parathyroid hormone. The discrepancy may be ascribed to the different immunoassays used for parathyroid hormone (traditional radioimmunoassay versus immunoradiometric assay for intact parathyroid hormone). Thus the low osteocalcin level during pregnancy may be related to the decreased parathyroid hormone level.

Parathyroid hormone and $1,25(OH)_2D$ can influence

the synthesis of osteocalcin. Parathyroid hormone produces an increase in bone resorption that, although it does not directly stimulate the synthesis of osteocalcin, results in an increase of the osteocalcin levels instead of increased parathyroid activity.[3] $1,25(OH)_2D$ stimulates the synthesis of osteocalcin by osteoblasts and promotes its release into the circulation.[4] Although $1,25(OH)_2D$ levels were high early in pregnancy and increased with advancing gestation, osteocalcin levels decreased toward the middle of pregnancy. Therefore the stimulatory effect of increasing $1,25(OH)_2D$ levels on the synthesis of osteocalcin may be overridden by the inhibitory effect of decreasing parathyroid hormone levels in early and midpregnancy. Serum osteocalcin levels increased in late pregnancy. This may be ascribed to the increase in both parathyroid hormone and $1,25(OH)_2D$ during this period. Free $1,25(OH)_2D$ has been reported to increase in late pregnancy.

Osteocalcin levels 6 weeks post partum were higher than those 3 days post partum, indicating an increased bone turnover in the late puerperium. Parathyroid hormone, calcitonin, and $1,25(OH)_2D$ levels were similar 3 days and 6 weeks post partum. However, parathyroid hormone levels were increased in both early and late puerperium. Thus it may be that long-term but not short-term parathyroid hormone stimulation leads to an increased production of osteocalcin by osteoblasts.

The changes in parathyroid hormone and osteocalcin levels during the puerperium may, in part, be ascribed to lactation. However, all women breast-fed their infants for at least 6 weeks post partum. Therefore we could not assess the effect of lactation per se on calcium-regulating hormones and osteocalcin levels during the puerperium.

The relationship between autoantibodies and intrauterine growth retardation in hypertensive disorders of pregnancy

Albert El-Roeiy, MD, Stephen A. Myers, DO, and Norbert Gleicher, MD
Chicago, Illinois

Abnormal levels of autoantibodies have recently been demonstrated in patients with hypertensive disorders of pregnancy and patients whose fetuses have intrauterine growth retardation. We determined total immunoglobulin levels (immunoglobulin G, immunoglobulin M, and immunoglobulin A) and a broad panel of autoantibodies (six antiphospholipid, four antihistone, and four antipolynucleotide antibodies) in 50 normotensive pregnant females, 19 patients with preeclampsia, and 18 patients with chronic hypertension to examine the relationship to intrauterine growth retardation. Mothers who were delivered of infants with intrauterine growth retardation demonstrated significantly more autoantibody abnormalities in the two hypertensive groups and in the normotensive control group as compared with patients delivered of appropriately grown infants. The most frequently observed autoantibody abnormalities were antiphospholipid antibodies and the most frequently observed among those were immunoglobulin G isotypes. Total immunoglobulin levels in both hypertensive and normotensive groups were identical. These results suggest a close association between the degree of B-cell activation and both severity of hypertensive diseases and development of intrauterine growth retardation in their offspring. (Am J Obstet Gynecol 1991;164:1253-61.)

Key words: Autoantibodies, preeclampsia, intrauterine growth retardation

The possible involvement of the immune system in the pathophysiology of at least some hypertensive disorders of pregnancy has recently attracted increasing attention.[1] A number of investigators have suggested that some cases of preeclampsia-eclampsia are associated with clinical autoimmune phenomena.[2-5] Alterations in humoral immune function in such patients include production of antibodies toward trophoblast antigens,[6] amniotic glycoprotein, placental and renal antigens,[7] lymphocytes,[8] and laminin.[2]

A correlation between intrauterine growth retardation (IUGR) and the severity of a particular hypertensive disorder is well documented in the literature.[9, 10] A significant incidence of IUGR has also been observed in patients with such connective tissues diseases as systemic lupus erythematosus.[11] Lockshin et al.[12] suggested that IUGR in these patients may be related to disease activity, which in turn correlates to the presence of autoantibody abnormalities. These observations led us to consider whether alterations in fetal growth in patients with hypertensive diseases of pregnancy may be related to abnormal maternal autoantibody production. The aim of this study was to examine selective parameters of B-lymphocyte activity in patients with hypertensive disorders of pregnancy and their relationship to IUGR in their offspring.

Material and methods

Study population. Serum samples from 50 consecutive normotensive and apparently normal pregnant patients (control group) from 29 consecutive patients with preeclampsia (18 mild and 11 severe) and from 18 patients with chronic hypertension (three with superimposed preeclampsia) were studied. All but two patients with preeclampsia were primigravidas. Mild and severe preeclampsia, respectively, were defined according to the criteria of the American College of Obstetricians and Gynecologists.[13] The presence of any one or more of the following signs or symptoms marked the preeclampsia as severe: blood pressure of 160 mm Hg systolic and 110 mm Hg diastolic on two occasions at least 6 hours apart; proteinuria of at least 5 gm/24 hours; oliguria (urinary volume of <400 ml/24 hours); cyanosis or pulmonary edema. The diagnosis of chronic hypertension was based on a history of hypertension either before pregnancy or before 20 weeks' gestation. Fourteen of 18 patients (78%) with this diagnosis were receiving methyldopa therapy (Aldomet, 1.5 to 3 gm/day) at the time of the first prenatal visit.

Superimposed preeclampsia was diagnosed after the occurrence of either an abrupt rise of blood pressure (>30 mm Hg in systolic or 15 mm Hg in diastolic pres-

sure) measured on two occasions 6 hours apart, or after a significant increase in the degree of proteinuria (>5 gm/24 hours), or both. Blood samples from all normotensive and hypertensive patients were drawn in labor within hours of delivery.

Normotensive control patients included 43 prospectively enrolled women delivered of infants with weights appropriate for gestational age (AGA) and seven patients delivered of infants with idiopathic IUGR. Control patients experienced no significant antepartum or intrapartum pregnancy complications. Neither study nor control patients showed any evidence of diabetes mellitus, rhesus isoimmunization, history or symptoms of autoimmune disease, chronic inflammatory disease, or drug abuse.

IUGR was defined as a gestational age–controlled birth weight below the 10th percentile of 2200 deliveries at Mount Sinai Hospital Medical Center in Chicago. Careful attention was paid to the accurate determination of correct gestational ages by reliable establishment of dates of last normal menses or ultrasonographic dating. Proteinuria was quantified by 24-hour urine collection in 14 of 29 patients with preeclampsia and four of 18 patients with chronic hypertension. The remaining patients underwent a semiquantitative assessment of proteinuria with a standard dipstick method (Ames Division, Miles Laboratories, Inc., Elkhart, Ind.). Blood urea nitrogen, creatinine, and uric acid were determined with a standard hospital autoanalyzer. Total platelet concentrations were established with a Coulter counter. Thrombocytopenia was defined as <100,000 platelets/ml and was verified by repeated sampling. All blood pressure levels were determined with a sphygmomanometer by recording the first and the fourth sounds as systolic and diastolic pressures. Mean arterial blood pressure levels were calculated from the systolic and diastolic blood pressures (diastolic + (systolic − diastolic)/3).

Immunologic studies. Total immunoglobulin G (IgG), total immunoglobulin M (IgM), and total immunoglobulin A (IgA) concentrations were measured with a routine radial immunodiffusion method.[14] The

autoantibody profile included autoantibodies to six phospholipids (cardiolipin, phosphatidylserine, phosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, phosphatidic acid), total histone (H1), and three histone subfractions (H2A, H3, and H4) and to four polynucleotides (single-stranded deoxyribonucleic acid [DNA], double-stranded DNA, polyinosinic acid, and polythymidylic acid). All autoantibodies were separately evaluated for IgG, IgM, and IgA isotypes. After venipuncture, all samples were allowed to clot, were centrifuged at 2500 *g* for 15 minutes, and then the serum samples were decanted. All serum samples were stored below −70° C and assayed simultaneously at the completion of the study. A detailed description of autoantibody assays has been previously reported.[15]

Briefly, microtiter plates were coated with the different antigens and blocked for nonspecific binding. Duplicate serum samples were diluted to 1:150 in phosphate-buffered saline solution with 10% fetal calf serum and were added and incubated for 12 hours at 4° C. Affinity-purified, alkaline phosphatase–conjugated goat antihuman IgG, IgM, and IgA (Sigma Chemical Co., St. Louis) in phosphate-buffered saline solution with 10% fetal calf serum were added. The plates were then washed and 1 mg/ml of *p*-nitrophenyl disodium phosphate (Sigma) in 1 mol/L diethanolamine and 0.5 mol/L magnesium chloride at pH 9.6 was added as substrate. The plates were fixed and read at 405 nm with a spectrophotometer (Biotek Inc., San Francisco). Control serum samples with elevated IgG and IgM antiphospholipid, histone, and polynucleotide antibodies as well as a blank well with no serum were assayed in parallel with each plate. An abnormal result was defined as an optical density above the 99% confidence interval for each autoantibody and isotype. This interval was determined at different gestational ages from 43 normotensive prospectively followed up control patients delivered of AGA infants. Seven normotensive patients delivered of infants with IUGR were excluded from establishment of the confidence interval.

Statistical analysis. We compared age, gravidity, gestational age, systolic/diastolic pressures, mean blood pressure, proteinuria, uric acid, creatinine values, and platelet counts between control and study groups with the Tukey-Kramer test.[16] The test corrects for an unequal number of patients in each group and for multiple comparisons.

With the assumption of complete independence be-

tween the variables, the probability of a single positive result in a patient depends on the number of assays (tests) performed, the definition of a positive antibody value, and the number of investigated patients. We consequently calculated the probability of one or more elevated antibodies, as expected for a binomial distribution when outcomes are equally likely.[17] In accordance, the expected number of patients to demonstrate one, two, three, and four elevated autoantibodies was 29%, 12.9%, 5.6%, and 2.4%, respectively, if all 42 isotypes were investigated. Consequently, only patients with five or more abnormally elevated autoantibodies were considered to demonstrate a significant B-cell activation. The same calculation revealed that three or more abnormal autoantibody elevations had to be considered significant if only one isotype (14 tests) was evaluated, three or more abnormalities were significant if only antiphospholipids were tested (18 tests), and two or more abnormalities if only antihistones and antipolynucleotides (12 tests each) were evaluated.

Contributing factors that may affect autoantibody production, such as age, gravidity, total immunoglobulin levels, methyldopa therapy, cigarette smoking, drug abuse, proteinuria, and systolic, diastolic, and mean blood pressure levels were included in a regression adjustment analysis. To evaluate whether the autoantibody profile was significantly different in the two hypertensive groups, a multivariant discriminant analysis was performed. The expected and actual number of autoantibodies and the incidence of birth weight under the 10th percentile were compared with the Fisher exact test. All statistical analyses were calculated with the Systat statistical computer package (Systat, Evanston, Ill.). All differences were assumed to be significant when $p < 0.05$ with two-tailed tests.

Results

Demographic data and laboratory profiles of all patients are described in Table I. Gestational ages in the various study groups did not differ significantly. The mean age of patients with chronic hypertension with AGA infants was higher than that of patients with mild as well as severe preeclampsia ($p < 0.05$) and normal control subjects ($p < 0.05$). The number of patients who smoked cigarettes or had a history of drug abuse was not statistically different between mothers who were delivered of AGA infants or infants with IUGR. All 18 patients with mild preeclampsia and six of 11 patients with severe preeclampsia were delivered of AGA infants. Five of 11 patients with severe preeclampsia and three of 18 patients with chronic hypertension were delivered of infants with IUGR. Preeclampsia was diagnosed in all three of these patients.

Proteinuria was significant only in those hypertensive patients delivered of infants with IUGR ($p < 0.05$). Platelet counts were significantly lower in patients with severe preeclampsia than those in normotensive patients and patients with mild preeclampsia ($p < 0.05$). Thrombocytopenia was observed in two of 11 patients with severe preeclampsia (one with and one without infants with IUGR) and in one of three patients with chronic hypertension who were delivered of an infant with IUGR. No significant differences were found in uric acid or creatinine values between hypertensive groups.

Total IgG, total IgM, and total IgA concentrations are presented in Table II. No significant differences were found between normotensive patients and the two hypertensive groups.

The number of elevated autoantibodies in hypertensive and control groups is presented in Fig. 1. Normotensive patients delivered of infants with IUGR demonstrated significantly more abnormally elevated antibodies than normotensive patients delivered of AGA infants ($p < 0.05$). However, even in the former group, only one patient exhibited more than five autoantibody abnormalities. In contrast, patients with preeclampsia and chronic hypertension, whether delivered of AGA infants or infants with IUGR, demonstrated a significant increase in autoantibody production over normotensive patients. It is more important, however, that within each hypertensive group, pregnancies that resulted in IUGR demonstrated significantly elevated autoantibody levels in comparison with pregnancies that resulted in AGA infants. No significant difference in autoantibody results was noted between patients with preeclampsia and chronic hy-

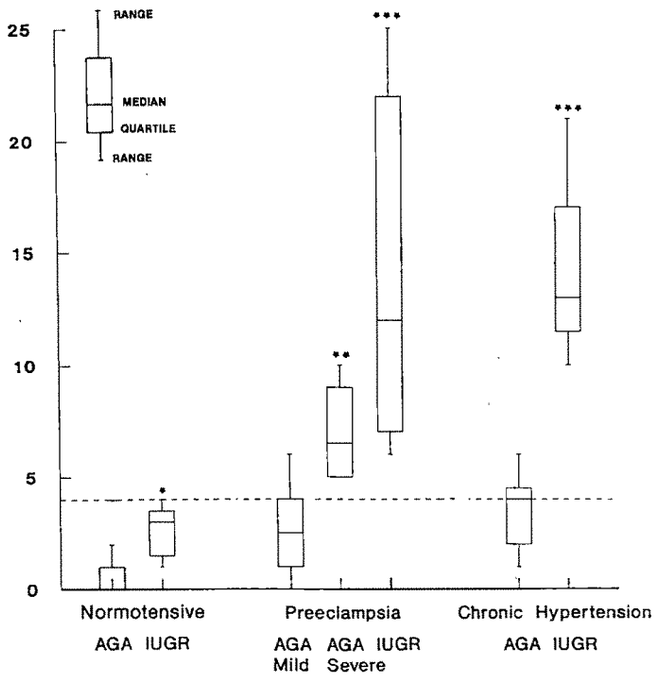

Fig. 1. Number of total autoantibodies (expressed by median and range) in normotensive and hypertensive groups. *One asterisk,* Significantly different from normotensive (AGA) group. *Two asterisks,* Significantly different from normotensive group (AGA and IUGR) and mild preeclampsia (AGA) ($p < 0.05$). *Three asterisks,* Significantly different from normotensive (AGA and IUGR) and hypertensive (AGA) groups ($p < 0.05$).

pertension who were delivered of AGA infants. Specific autoantibody abnormalities are shown in Fig. 2. The most frequently elevated autoantibodies were antiphospholipid, followed by antihistone and antipolynucleotide antibodies.

The highest number of elevated antibodies was found in patients with severe preeclampsia and chronic hypertension who were delivered of infants with IUGR. The most frequently observed antiphospholipid antibodies were antiphosphatidylglycerol, antiphosphatidylinositol, and antiphosphatidic acid antibodies. Only two of five patients with severe preeclampsia and one of three patients with chronic hypertension who were delivered of infants with IUGR demonstrated significantly elevated IgG anticardiolipin antibodies. In contrast, nine of 11 patients (82%) with severe preeclampsia and three of three patients (100%) with chronic hypertension who were delivered of infants with IUGR showed significantly elevated antibodies toward phosphatydilglycerol, phosphatydilinositol, and phosphatidic acid ($p < 0.05$). The highest incidence of antihistone antibodies was found in women with chronic hypertension, who were delivered of infants with IUGR and the most frequent antibodies observed were anti-H2A and anti-H3 subfractions. No significant antipolynucleotide abnormalities were observed in patients with either preeclampsia or chronic hypertension or in normotensive control patients.

An analysis of autoantibody isotypes (Fig. 3) indicates that IgG antibodies were most frequently elevated ($p < 0.05$). The highest incidence was found in hypertensive patients delivered of infants with IUGR. No significant differences in this regard were noted between the two hypertensive groups delivered of infants with IUGR. No correlation could be found between the levels of autoantibodies and the levels of total immunoglobulins IgG, IgM, and IgA.

Regression adjustment analysis of all previously noted potentially confounding variables excluded any of these parameters as contributing factors to the observed differences. Multivariant discriminant analysis indicated that the autoantibody profiles of hypertensive patients delivered of infants with IUGR were significantly different from both normotensive and hypertensive patients delivered of AGA infants (Wilks' Λ 0.11, $p < 0.01$).

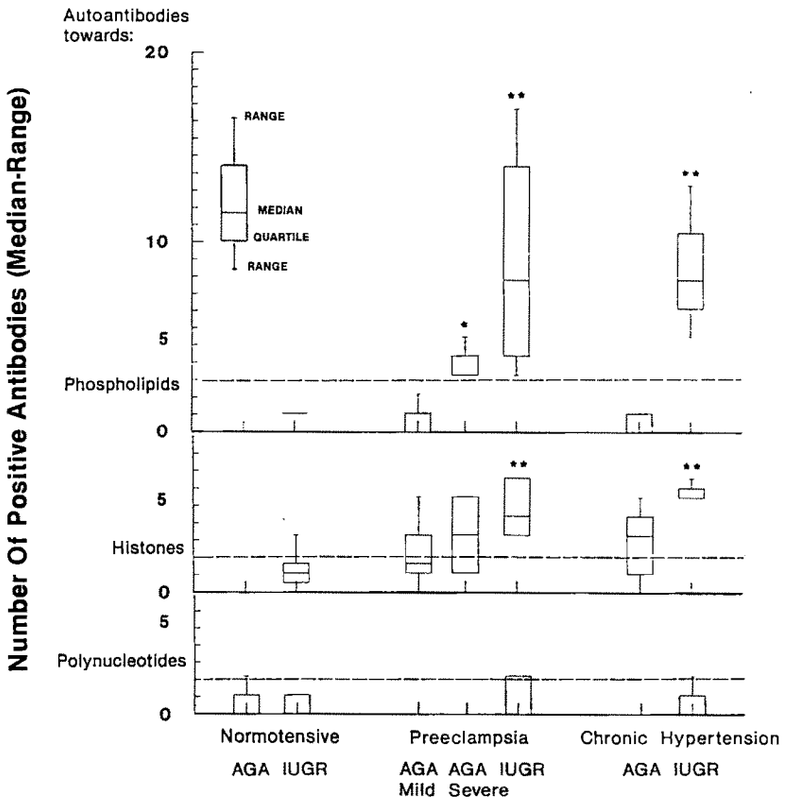

Fig. 2. Distribution of autoantibodies toward phospholipids, histones, and polynucleotides in normotensive and hypertensive groups. *One asterisk,* Significantly different from normotensive group (AGA and IUGR) ($p < 0.05$) and mild preeclampsia (AGA) ($p < 0.05$). *Two asterisks,* Significantly different from normotensive (AGA and IUGR) and hypertensive (AGA) groups ($p < 0.05$).

Comment

The purpose of this study was to examine the autoimmune response of patients with hypertensive disorders of pregnancy in relationship to the development of IUGR in offspring. As expected,[9, 10] IUGR occurred significantly more often in pregnancies with severe hypertension compared with patients with mild or no disease. Similarly, autoantibody production is related to severity of disease. It is important that mothers delivered of infants with IUGR demonstrated significantly more autoantibody production compared with mothers delivered of AGA infants in both hypertensive and normotensive groups.

One of the first observations to link IUGR and hypertensive disorders of pregnancy was made by McBurney[18] in 1947. Wildschut et al.[10] were able to demonstrate that multiparas with chronic hypertension had an increased incidence of IUGR compared with normotensive multiparas. Lin et al.[19] further expanded this observation by demonstrating the synergistic effect between hypertension and proteinuria in association with IUGR. In contrast to chronic hypertension, the relationship between pure preeclampsia and IUGR is less clear.[20] It appears that IUGR occurs in patients with preeclampsia only if the onset of disease is early and the disease is severe. Plouin et al.[21] observed that the onset of hypertension between 27 and 36 weeks' gestation was associated with the highest incidence of IUGR. Sibai[9] demonstrated a strong association between the severity of the disease, presence of proteinuria, and the appearance of IUGR.

Several studies have shown that patients with chronic hypertension and superimposed preeclampsia experience the highest incidence of IUGR. Wildschut et al.[10] reported that 42% of multiparas and 24% of nulliparas who had chronic hypertension with superimposed preeclampsia were delivered of infants with IUGR. Similar results were also reported by Sibai[9] and Gleicher et al.[22] Chesley[23] noted that patients with superimposed preeclampsia exhibited the worst perinatal outcome among all hypertensive patients. Our findings are consistent with a general pattern of increasing severity of disease, increasing incidence of IUGR, and increasing activation of the maternal immune system.

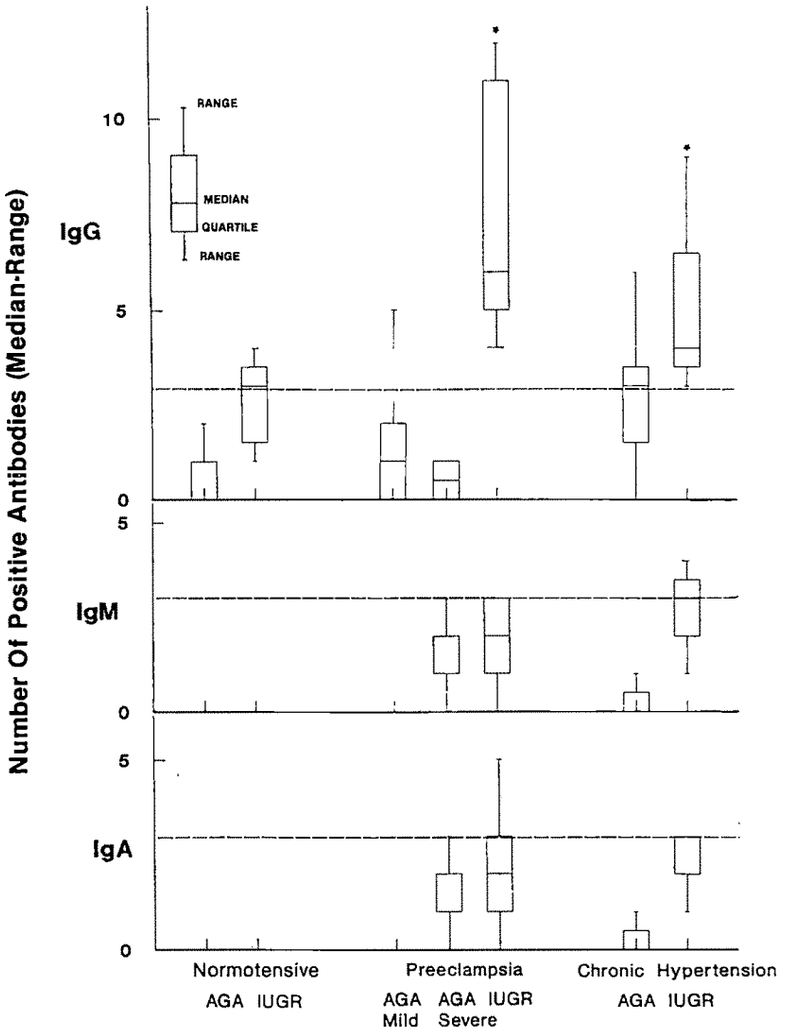

Fig. 3. Distribution of autoantibody isotypes in normotensive and hypertensive groups. *Asterisk*, Significantly different from normotensive (AGA and IUGR) and hypertensive (AGA) groups ($p < 0.05$).

Because the groups did not differ in the number of patients who smoked cigarettes or had a history of drug abuse, the mechanisms that cause diminished fetal growth are puzzling and raise some intriguing questions. Can the presence of abnormal autoantibodies contribute to the formation of vascular lesions in the placenta, which in turn compromise uteroplacental blood flow? Such lesions have been reported in placentas from patients delivered of IUGR infants.[24] The deposition of immune complexes,[25] complement components,[26] and the presence of chronic villitis in placentas of patients with hypertensive disorders,[27] autoimmune diseases,[28] and in placentas from idiopathic infants with IUGR[24, 27] lends support to such a concept.

Endothelial damage and the subsequent release of vasoactive compounds is recognized as part of the pathophysiology for some forms of hypertension in pregnancy.[29, 30] Thromboxane A_2 is released by vascular endothelium in the presence of lupus anticoagulant or antiphospholipid antibodies.[31] In this study, antiphospholipid antibodies were the most frequently recorded abnormalities in pregnancies, resulting in infants with IUGR. Those antibodies, and especially the IgG isotypes, have been associated with the presence of lupus anticoagulant and a predisposition toward arterial and venous thrombosis.[32] In this study antiphospholipid antibodies of the IgG isotype were most often produced and were demonstrated especially in pregnancies with IUGR. It is thus tempting to speculate that these autoantibodies may account for some of the placental damage seen in hypertensive disorders of pregnancy complicated by IUGR.

In pregnancies complicated by IUGR autoantibodies to phosphatidylglycerol, phosphatidylinositol, and phosphatidic acid occurred significantly more often than did anticardiolipin antibodies. Thus patients delivered of infants with IUGR either demonstrated a broad polyclonal activity or the production of specific clones that cross-reacted with different antigenic phospholipid determinants. Moreover, this finding questions the concentration by some investigators on anticardiolipin antibodies and lupus anticoagulant,[33, 34] a correlation that has also been questioned by others.[35-37] Thus these observations suggest that the production of antiphospholipid antibodies is not confined to a single autoantibody.

The highest incidence of antihistone antibodies was noted in patients with chronic hypertension and especially in those delivered of infants with IUGR. All the affected patients had methyldopa therapy. This drug is known to induce antihistone antibodies and, at times, even clinical symptoms consistent with systemic lupus erythematosus.[38] Whether the detection of antihistone antibodies in this study is drug-related or disease-related remains to be determined.

If autoantibody production can affect fetal growth, then suppression of this production may decrease the incidence of IUGR. Whereas clinical trials of immunosuppression have not been attempted so far, antithrombotic therapy, which can counteract the thrombotic effect of antiphospholipid antibodies, has recently been reported. Low-dose aspirin counteracts the excess production of thromboxane A_2[29] that may be induced by antiphospholipid antibodies.[31] Wallenburg et al.[39] used aspirin and dipyridamole to treat normotensive pregnant women who previously were delivered of infants with idiopathic IUGR. Recurrent fetal growth retardation occurred in 13% of treated and 61% of untreated pregnancies. The same author[40] also reported that a similar low-dose aspirin protocol caused a decrease in the subsequent occurrence of maternal preeclampsia. These observations suggest that treatment directed at the effect of abnormal B-cell activation may be useful to prevent IUGR and may have benefit in the treatment of hypertensive disorders of pregnancy.

Umbilical arterial and venous acid-base and blood gas values and the effect of chorioamnionitis on those values in a cohort of preterm infants

Gary D.V. Hankins, Lt Col, USAF, MC, Russell R. Snyder, Lt Col, USAF, MC, and Edward R. Yeomans, Maj, USAF, MC

San Antonio, Texas

Umbilical arterial and venous acid-base and blood gas values in uncomplicated premature births are similar to values that are reported in term infants and are unaffected by birth weight or gestational age. In this group of patients chorioamnionitis had no significant effects on umbilical arterial acid-base or blood gas values or on the percentage of patients that were born with acidemia. Apgar scores were significantly lower in the group with chorioamnionitis in spite of a virtual absence of acidemia, which again suggests that low Apgar scores alone do not confirm a diagnosis of birth asphyxia. (AM J OBSTET GYNECOL 1991;164:1261-4.)

Key words: Apgar scores, chorioamnionitis, cord acid-base status, preterm

Assessment of acid-base status by means of umbilical cord blood sampling provides an objective method of evaluation of either fetal or newborn condition.[1, 2] In contrast, the Apgar score is a very subjective measurement, which may vary substantially depending on the skill, experience, and bias of the individual who assigns the score. Further, in regard to the preterm infant, a low Apgar score has not been shown to be predictive of acidemia or of asphyxia.[3]

To date, there is a paucity of information on umbilical arterial acid-base and blood gas determinations in preterm infants and an absence of published information about umbilical venous blood values. Ramin et al.[4] found no significant differences in umbilical arterial acid-base or blood gas values in preterm infants compared with term infants. They also found no significant

differences when preterm infants were stratified according to birth weight.

The purpose of this investigation was to provide additional information regarding umbilical arterial values and to report umbilical venous values in infants with low birth weight. Additionally, we sought to determine the effects of chorioamnionitis on the newborn's immediate metabolic condition as reflected by umbilical cord pH and blood gas values and to compare this information to that provided by Apgar scores.

Patients and methods

Woman and infant pairs that were included in this study were delivered at Wilford Hall United States Air Force Medical Center between October 1984 and April of 1990. The study population consisted of all women whose fetuses weighed <2500 gm at birth, were <37 weeks' gestational age, and for whom umbilical cord blood pH and blood gas determinations were available. All complications of pregnancy except premature labor with or without rupture of fetal membranes and/or chorioamnionitis were excluded from analysis. Clinical diagnosis of chorioamnionitis consisted of maternal fever and uterine tenderness or uterine tenderness and concomitant fetal tachycardia. Although the latter criteria were sufficient to make the initial clinical diagnosis and to institute antibiotic therapy, it was noted that in each instance these women had fevers before delivery. All cases of preeclampsia, intrauterine growth retardation, and fetal distress were excluded. Specifically, fetal distress that was sufficient to warrant exclusion from analysis consisted of a fetal heart rate pattern that was of enough concern to result in either an operative vaginal delivery or a cesarean delivery. Umbilical cord prolapse, which is uniformly treated with cesarean delivery, also was categorized as fetal distress. The antepartum, intrapartum, and postpartum records of each of these women were carefully reviewed to complete the data base.

Among the 110 women-infant pairs, 24 had chorioamnionitis and 86 had no complications except for premature labor and/or premature rupture of membranes. The latter group was managed expectantly in the absence of signs or symptoms of infection or fetal distress. The 86 infants without chorioamnionitis were subdivided, on the basis of birth weight, into categories of ≤1499, 1500 to 1999, and 2000 to 2499 gm. In all cases gestational age was well established by a combination of menstrual data, obstetric examination, and ultrasonographic evaluation.

At our institution, umbilical arterial and venous pH and blood gas determinations are routinely performed at all deliveries, as previously described.[2] All specimens are analyzed within 5 minutes of collection on an ABL-2 analyzer (Radiometer, Copenhagen), which is maintained in the neonatal intensive care unit. Two blood gas analyzers operate continuously and are calibrated against known standards several times daily. They are also autocalibrated before each individual blood analysis. Fetal acidemia was defined as an umbilical arterial pH <7.20 with further stratification to pH values <7.10 and <7.0 to more stringently define acidemia.

Apgar scores were assigned by the pediatricians in attendance at each of the deliveries. Five infants in the group with chorioamnionitis and seven in the group without evidence of infection were not assigned Apgar scores because of early intubation and its effects on the Apgar score.

Statistical significance was determined by means of the two-tailed t test, χ^2 analysis, or the Fisher exact probability test, as appropriate. Significant differences were determined at $p < 0.05$.

Results

The umbilical arterial and venous acid-base values, which were stratified by birth weight, are shown in Tables I and II, respectively, for those infants with no evidence of chorioamnionitis. No significant differences existed for any blood gas or acid-base parameter relative to birth weight. An absolute pH <7.20 was noted in one of 12 infants who weighed <1499 gm, three of 20 infants who weighed 1500 to 1999 gm, and seven of 54 infants who weighed 2000 to 2499 gm, and there was no significant difference for any birth weight category.

Comparison of acid-base and blood gas parameters from uncomplicated term deliveries, as previously reported by our institution,[2] and of values in preterm deliveries with and without chorioamnionitis can be found in Table III. The only significant difference that

Preterm	86	7.28 ± 0.07	47.96 ± 9.41	19.47 ± 6.93	22.04 ± 2.93	−4.06 ± 3.26
Preterm-chorioamnionitis	24	7.26 ± 0.10	48.71 ± 14.29	17.98 ± 7.06	21.07 ± 3.75	−5.29 ± 4.54
Venous						
Term	146	7.35 ± 0.05	38.2 ± 5.6	29.2 ± 5.9	20.4 ± 2.1	—
Preterm	86	7.34 ± 0.06	40.34 ± 6.38	27.58 ± 7.5	21.25 ± 2.32	−4.04 ± 2.92
Preterm-chorioamnionitis	24	7.32 ± 0.11	41.19 ± 13.6	29.7 ± 9.21	19.9 ± 4.06*	−5.63 ± 4.48

Data are presented as mean ± SD.
*$p = 0.044$, preterm versus preterm-chorioamnionitis.

was noted was a lower bicarbonate value in the umbilical venous blood of the preterm infants with chorioamnionitis versus those that were uninfected ($p = 0.044$). With respect to pH values <7.20, four of 24 (16.7%) infants with chorioamnionitis and 10 of 86 (11.6%) infants without infection had this degree of acidemia (p = NS). More severe acidemia was rare; a pH <7.10 was noted in two of 24 infants with chorioamnionitis versus one of 86 uninfected infants. A pH <7.0 was noted in one infected infant and in one uninfected infant.

Maternal demographics and puerperal variables were analyzed according to the presence or absence of chorioamnionitis. No significant differences existed for maternal age, route of delivery, breech versus vertex presentation, length of the first or second stage of labor, or percent of infants that required endotracheal intubation at delivery. Those neonates whose courses were complicated by chorioamnionitis were significantly younger (209.5 ± 21.1 vs 235.8 ± 19.8 days, mean ± SD, $p < 0.00001$) and correspondingly much smaller (1562 ± 502 vs 2018 ± 437 gm, mean ± SD, $p < 0.00001$) than those that were born prematurely but without chorioamnionitis. Additionally, as a group the mean Apgar score at 1 minute was depressed relative to that of those infants without infection (5.3 ± 2.8 vs 6.9 ± 2.0, mean ± SD, $p < 0.006$). Infants with chorioamnionitis also had a higher percentage of Apgar scores <3 at 1 minute (5/19 vs 5/79, $p < 0.01$) and <7 at 5 minutes (5/19 vs 8/79, $p < 0.05$) than did their counterparts who were not infected. The mean Apgar score at 5 minutes was 7.6 ± 2.0 in infants with chorioamnionitis and 8.0 ± 1.7 in those without infection (p = NS).

Comment

The objective of this investigation was to establish normative data for a population of patients with otherwise uncomplicated premature labor and delivery and to compare our results with data that have been previously published. Umbilical arterial acid-base and blood gas parameters in the population reported here are very similar to those reported by Ramin et al.[1] for uncomplicated premature deliveries. In accordance with those investigators, we also found no statistically significant effects on the basis of birth weight, or by extrapolation for gestational age, on any parameter measured.

We also report umbilical venous acid-base and blood gas values for 86 preterm deliveries, which were otherwise uncomplicated. Birth weight, as well as arterial specimens, had no significant effect on any parameter that was measured. Further, comparison of both the arterial and venous values for uncomplicated term deliveries, as previously reported,[2] reveals no effect of gestational age on acid-base or blood gas values.

The second major objective of this study was to quantify the effect of chorioamnionitis in the premature infant on the immediate metabolic condition at birth. Although the umbilical arterial pH was somewhat lower (7.26 vs 7.28) in those infants with chorioamnionitis and the base excess was somewhat higher (−5.29 vs −4.06)

than in the preterm infants without infection, neither value achieved statistical significance. A similar trend was seen in the umbilical venous specimens in regard to pH and base excess; however, in this instance the concentration of bicarbonate was lower ($p = 0.044$). With the use of absolute pH values to define acidemia, we again found no significant difference in those infants with chorioamnionitis relative to those who were not infected. Significantly, factors that might have influenced these values (such as length of labor, abnormal presentations, or operative abdominal or vaginal delivery) were not significantly different between those with and those without chorioamnionitis. The lower birth weights and less advanced gestational ages, which are both highly significant in infants who were infected relative to infants who were not infected, also cannot independently account for any of the differences. However, infection did appear to result in earlier delivery as compared with that in the group without an identifiable precipitant of the labor and/or amniorrhexis.

If Apgar scores had been used to predict metabolic status, they would have predicted a much greater effect in those infants with chorioamnionitis than was shown to exist by acid-base assessment. The analysis of low Apgar scores excluded those infants who were intubated by a pediatrician at birth. This exclusion was elected because in many instances the intubation was performed prophylactically and purely on the basis of gestational age. Reanalysis to include low Apgar scores and those infants who were intubated did not alter the results, statistical significance, or conclusions.

The Apgar score alone has been shown to be an unreliable predictor of neonatal acidemia and asphyxia in the preterm infant.[3, 5] Apgar scores have also been judged insufficient in and of themselves to define asphyxia in term infants.[1, 6, 7] In addition, Mayberry et al.[8] have shown that significantly more infants with chorioamnionitis have low 1-minute (20% vs 5%) and 5-minute (3% vs 1%) Apgar scores than do infants without infection. The population that was reported on by these investigators consisted primarily of term gestations. Current data further suggest the inadequacy of the Apgar score as a marker of birth asphyxia in preterm infants with chorioamnionitis since depressed Apgar scores in this group were seldom associated with umbilical arterial acidemia.

In conclusion, umbilical arterial acid-base and blood gas values in the cohort of preterm infants that are reported on here are similar to those reported on by other investigators.[4] Additionally, they are not significantly different from values reported in uncomplicated term deliveries[5] and are not affected by birth weight or by the extrapolated gestational age. Chorioamnionitis in the preterm infant did result in significant depression of Apgar scores but had no effect on acid-base or blood gas values and did not lead to acidemia. Accordingly, the diagnosis of birth asphyxia in the preterm infant, with or without chorioamnionitis, requires cord blood analysis; the Apgar score alone is not sufficient.

Cervical human papillomavirus deoxyribonucleic acid and cytologic evaluations in gynecologic outpatients

Pekka Nieminen, MD,[a] Valeria R.X. Soares, MSc,[a] Markku Aho, MD,[a] Ervo Vesterinen, MD,[a] Eeva Savia, MD,[a] Antti Vaheri, MC,[b] and Jorma Paavonen, MD[a]
Helsinki, Finland

We studied the prevalence and cytologic manifestations of human papillomavirus deoxyribonucleic acid among 2668 gynecologic outpatients. The study population consisted of 1573 women who came into the emergency room, 623 women from an abortion clinic who were seen because of induced first-trimester abortion, and 472 women who had been referred to a colposcopy clinic because of an abnormal Papanicolaou smear finding. A dot blot technique was used for the detection of human papillomavirus types 6/11, 16/18, and 31/33/35. The prevalence of human papillomavirus deoxyribonucleic acid was 4.4% in the emergency room population, 8.8% in the abortion clinic population, and 31.4% in the colposcopy clinic population. Human papillomavirus type 16/18 was most prevalent (3.5%), followed by human papillomavirus type 31/33/35 (3.1%), and human papillomavirus type 6/11 was least prevalent (2.1%). Of all unselected human papillomavirus deoxyribonucleic acid–positive women who were enrolled from the emergency room or from the abortion clinic, 73% had normal cytologic evaluations. Twenty-five percent had benign atypia, and 2% had dyskaryotic changes. No human papillomavirus deoxyribonucleic acid type-specific differences were detected in the distribution of cytologic atypias. (Am J Obstet Gynecol 1991;164:1265-9.)

Key words: Cervical HPV DNA, cytology

There is increasing interest in the epidemiology of human papillomavirus (HPV) infection in unselected populations. Cytologic studies that are based on the detection of koilocytes in cervical cell samples suggest relatively low prevalence, whereas studies that utilize HPV deoxyribonucleic acid (DNA) hybridization techniques or polymerase chain reaction suggest high prevalence of HPV DNA both among selected and unselected women.[1-11] The prevalence of HPV DNA seems to vary greatly depending on the detection technique used, the number of HPV types that are studied, the type of population that is studied, and the geographic origin of the study population. Furthermore, interlaboratory variation in the prevalence estimates of HPV DNA has probably been underestimated.

Although the presence of HPV DNA does not necessarily indicate an active papillomavirus infection, it is important to learn more about the epidemiologic correlates of HPV DNA in order to develop clinical management strategies. This study was undertaken to determine the overall prevalence of HPV DNA, the prevalence of selected HPV DNA types, and cytologic correlates of HPV DNA among women who were seen in a metropolitan gynecologic outpatient clinic. On the basis of the screening results a study was set up, in which women, who were primarily HPV DNA-positive but had normal cervical cytologic evaluations, were followed up. These results are to be reported later.

Patients and methods

Study population. The study was conducted at the Department of Obstetrics and Gynecology at University Central Hospital in Helsinki, Finland, between February 1988 and December 1988. The study population consisted of 1573 consecutive women who came into the emergency room of the outpatient clinic for the first time, 623 consecutive women who were seen because of induced first-trimester abortion, and 472 consecutive women who were referred to a colposcopy clinic because of an abnormal cervicovaginal cytologic (Papanicolaou) smear. We excluded women who had undergone hysterectomy, who had taken antibiotics during the previous 2 weeks, or who had been examined for the same problem in the same clinic within the last month.

Patient evaluation. All women underwent a standard gynecologic examination. Cervicovaginal cyto-

logic smear (Papanicolaou smear) was first taken with an Ayres spatula and by swabbing the endocervical canal with the Cytobrush (Medscand AB, Malmö) cervical sampler. The Papanicolaou smears were stained with modified Papanicolaou stain and reviewed by one cytologist who had no knowledge of the clinical or laboratory findings. The cytologic diagnosis of koilocytosis was based on the presence of characteristic "halo" cells with cytoplasmic perinuclear clearing.[12] The presence of dyskeratosis, binucleation, parakeratosis, or other mild cytologic abnormalities (benign atypias that were not consistent with dysplasia) was also noted.[13] When dyskaryotic changes were noted, the smears were interpreted as suggestive of dysplasia regardless of the presence or absence of koilocytosis.[14] Dyskaryotic smears were further classified as suggestive of mild, moderate, or severe dysplasia, or of carcinoma in situ according to standard criteria.[15]

Detection and typing of HPV DNA. Samples for the detection of HPV DNA were taken from the endocervix and from the transformation zone with a cotton-tipped swab and placed into specimen transport media (ViraPap specimen collection kit, Life Technologies Inc., Gaithesburg, Md.). Phosphorus 32–labeled ribonucleic acid probes for HPV types 6, 11, 16, 18, 31, 33, and 35 were used for detection of HPV DNA by dot blot hybridization (Virapap and Viratype, Life Technologies Inc.). The Virapap test detects HPV types 6, 11, 16, 18, 31, 33, and 35 as a cocktail, and the Viratype test distinguishes HPV types 6 or 11, 16 or 18, and 31, 33, or 35 as three different HPV DNA groups. The samples were first incubated with sample preparation reagent for 1 hour at 37° C. After cell lysis, 250 μl was removed and transferred to new tubes. These samples were treated with sample diluent (15 minutes at room temperature) to achieve DNA denaturation, applied to a presoaked nylon membrane in a 25-well ViraPap filter manifold (Life Technologies Inc.) and filtered under vacuum. Thereafter the filter was transferred to a reaction tray, and 5 ml of prewarmed prehybridization reagent was added. After prehybridization in a water bath (60° C) for 30 minutes, membrane-bound HPV-target DNA was hybridized to full-length ribonucleic acid transcripts that are homologous to HPV genotypes 6, 11, 16, 18, 31, 33, and 35 under stringent conditions (60° C for 2 hours). After three washes, the membranes were treated with ribonuclease for 15 minutes at 37° C to remove unhybridized probe and again washed three times at 60° C under highly stringent conditions. Bound probe was detected by autoradiographic exposure to Kodak X-Omat AR x-ray film (Eastman Kodak Co., Rochester, N.Y.) with intensifying screens at −70° C. The exposure time varied from 1 to 3 days. The signal was interpreted by comparison to negative controls, low-positive controls, and high-positive controls. The specimen was considered positive if the intensity of the autoradiographic signal was stronger than that of the low-positive control (Fig. 1). All autoradiographs were independently interpreted by three of the authors. The interobserver agreement was 97%. Discordant results

were discussed by the three authors until consensus was reached. The ViraType HPV DNA typing kit (Life Technologies Inc.) applied the same procedures as those that were described for the ViraPap kit, with the following exceptions. After cell lysis, 450 μl was removed and treated with sample diluent to achieve DNA denaturation. The samples were then applied in equal aliquots to three nylon membranes and filtered under vacuum. After prehybridization, the membranes were hybridized with three separate probe mixes specific for HPV types 6/11, 16/18, or 31/33/35. The hybridization conditions, all remaining wash steps, and autoradiography were the same as those described for the ViraPap test.

The limits of detection of HPV DNA with ViraPap and ViraType tests are approximately 3 pg for ViraPap and 1 pg for ViraType.[16]

Statistical methods. Comparisons between the study groups with and without HPV DNA were performed either by the χ^2 test for proportions or Student's *t* test for means.

Results

Demographic characteristics. Selected demographic characteristics of the study populations are shown in Table I. HPV DNA-positive women were younger, had lower parity, and more often had a history of sexually transmitted diseases than HPV DNA-negative women. Number of lifetime sexual partners was also higher, but the difference was not statistically significant. There were no differences in contraceptive methods, smoking habits, or age at the first intercourse between the two groups. However, no differences were observed among the three study populations—emergency room, abortion clinic, and colposcopy clinic—in any of these parameters, except in the history of sexually transmitted diseases (Table I).

Type-specific prevalence of HPV DNA. The prevalence of HPV DNA was 4.4% in the emergency room clinic population, 8.8% in the abortion clinic population, and 31.4% in the colposcopy clinic population (Table II). The prevalence of HPV 16/18 was somewhat higher (3.5%) than that of HPV 31/33/35 (3.1%) or HPV 6/11 (2.1%). Thirty-eight patients (1.4%) tested positive for more than one of the three HPV groups, which represented 14.0% of all DNA-positive findings. Less than 1% of the women who were seen in the emergency room or in the abortion clinic had macroscopically visible genital warts, whereas 15% of the women who were seen in the colposcopy clinic had visible genital warts.

Cytologic correlates of HPV DNA. We also analyzed cytologic findings in relation to genital HPV infection. Simultaneously taken HPV DNA samples and cytologic

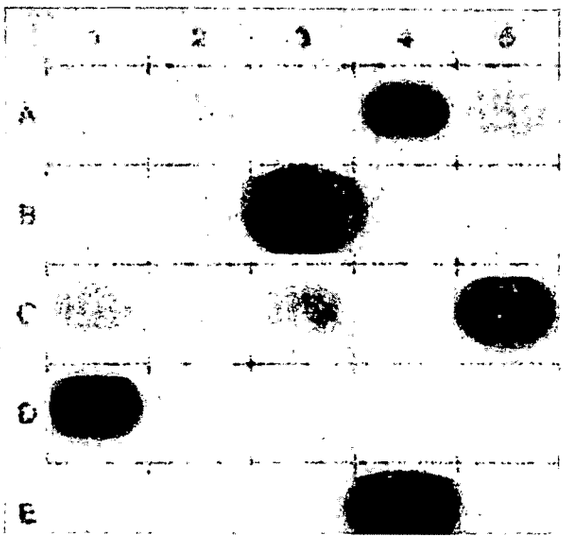

Fig. 1. Autoradiograph from a ViraPap test. *Row A, column 3* is "negative control," *A4* is "high-positive" control, and *A5* is "low-positive" control. Sample intensities below low-positive control (e.g., *A2*) are interpreted to be HPV DNA negative.

smears were available from 236 of 272 HPV DNA-positive women, and the control group consisted of 228 consecutive HPV DNA-negative women who were seen in the emergency room or in the abortion clinic. Among unselected women (emergency room and abortion clinic populations) (Table III) who tested positive for HPV DNA, 73% (74/102) had normal cytologic evaluations, 25% (26/102) had benign atypia, and 2% (2/102) had dyskaryosis. In the HPV DNA-negative group 92% (208/228) had normal cytologic evaluations, 2% (4/228) had dyskaryosis, and the remaining 6% (16 of 228) had benign atypia. Thus any atypia was present in 27% of the HPV DNA-positive women and in 8% of the HPV DNA-negative women. The difference in the overall distribution of cytologic findings between HPV DNA-positive and HPV DNA-negative women was statistically significant ($p < 0.001$). When the cytologic findings were correlated with specific HPV types, no significant differences were observed (Table III).

Women who were enrolled from the colposcopy clinic ($n = 472$) had, as expected, clearly more cytologic abnormalities (71%). In this group HPV type 16/18 and HPV type 31/33/35 were more often associated with dyskaryosis than was HPV type 6/11, but the differences were not significant (33% and 38% vs 25%, respectively) (data not shown).

Comment

We studied the prevalence of cervical HPV DNA by dot blot hybridization in a large number of women who visited a gynecologic outpatient clinic of a major university hospital in Helsinki, Finland. The prevalence of HPV DNA was 4.4% among unselected women who came into the emergency room, 8.8% among unselected women who were seeking induced abortions, and 31.4% among women who were referred to the colposcopy clinic because of an abnormal finding in a Papanicolaou smear. In earlier reports the prevalence of cervical HPV DNA has varied from 0.5% to 35%, although direct comparison among different studies is difficult because of differences in the hybridization techniques that were used.[11, 17] In many studies, however, only a limited number of HPV types (usually 6, 11, 16, and 18) have been studied, and the study populations have generally been more or less selected. HPV DNA has been detected (by Southern blot, dot blot, or in situ hybridization) in 30% to 91% of nonpregnant women who have cytologic evidence of cervical intraepithelial neoplasia and in 1% to 13% of nonpregnant women who have normal cytologic evaluations. In this study the prevalence of HPV DNA in unselected women from the emergency room was relatively low as compared with previous reports. However, among women from the abortion clinic, the prevalence was clearly higher, which is not surprising since these women had more lifetime sex partners and more often had a history of sexually transmitted diseases, although they were younger. No differences were observed between HPV DNA-positive and HPV DNA-negative women in parity, method of contraception, or smoking, which is somewhat surprising since previous studies have suggested that smoking and use of oral contraceptives are risk factors for HPV infection and cervical intraepithelial neoplasia.[18, 19] However, adjustments for duration and frequency of smoking or duration of use of oral contraceptives might have revealed significant differences between the groups.

Overall, only 14% to 20% of all positive HPV DNA findings were types 6 and 11. HPV types 16 and 18 were most prevalent and accounted for almost 50% of all unselected HPV DNA-positive women. Kiviat et al.[8] and Lorincz et al.[20] have reported similar findings in previous studies. This suggests that HPV types 16 and 18 are the most prevalent HPV types among individuals who do not have exophytic condylomas. We do not know whether these women are at increased risk for cervical neoplasia or how they should be managed. The high frequency of HPV types 16 and 18 DNA in unselected women and the decreasing incidence of cervical cancer in industrialized countries suggest that the risk of invasive cancer to individuals with HPV type 16 or HPV type 18 DNA is very low.

Although there is a tendency to assume that HPV DNA indicates HPV infection, this is not necessarily true. It is more likely that in many cases HPV DNA merely reflects the presence of virus or viral particles and not active infection. Before definitive conclusions from the link between HPV DNA and cervical cancer solely on the basis of the presence of HPV DNA can

be drawn, more studies of the transmission and natural history of HPV DNA are needed.

We found that nearly three fourths of the unselected HPV DNA-positive women had normal cytologic evaluations, and of all women with normal cytologic evaluations 4.5% tested positive for HPV DNA. In previous studies among women with normal cytologic findings, HPV DNA has been detected in 1% to 13% of subjects.[17] Although cytologic atypias (benign atypias and dyskaryosis) were more common among HPV DNA-positive women than among HPV DNA-negative women, no significant differences were seen among different HPV DNA types. These results differ from earlier reports, which have consistently shown that HPV types 16 and 18 are associated with dyskaryosis.[2, 3, 5, 20-24] One explanation is that in our study only few women had changes that were consistent with cervical epithelial neoplasia, and in fact, none had changes that were consistent with cervical epithelial neoplasia 2 or 3. HPV types 16 and 18 are more strongly associated with cervical epithelial neoplasia 2 to 3 than with cervical epithelial neoplasia 1.[25] Furthermore, although the prevalence of HPV types 16 and 18 and HPV types 31, 33, and 35 is commonly higher than that of HPV types 6 and 11, it is obviously higher also among women with cervical epithelial neoplasia. This might partly affect the interpretation of results, if the study population is selected on the basis of existing cervical epithelial neoplasia.

Previous HPV prevalence studies and annual incidence rates of cervical cancer suggest that up to 3% of HPV-positive women will have cervical cancer in 20 to 50 years.[7, 21, 26, 27] Natural history studies that utilize cytologic and colposcopic findings among women who are free of symptoms are also needed to determine cofactors that are of importance in the development of cervical neoplasia among women with or without cervical HPV DNA.

A prospective genetic study of complete and partial hydatidiform moles

Sylvia D. Lawler, MD,[a] Rosemary A. Fisher, PhD,[b] and Joan Dent, SRN[b]
London, England

Two hundred two hydatidiform moles were classified by pathologic features and ploidy into partial or complete moles. Further classification was made by using genetic polymorphisms, the diagnosis being refined by deoxyribonucleic acid technology. Among 51 partial hydatidiform moles, 44 triploids, two tetraploids, and one diploid were identified. Informative triploid partial hydatidiform moles had one maternal and two paternal sets of chromosomes, the likely origin being dispermy. Among 149 complete hydatidiform moles, one was haploid, one was triploid, and 105 were shown to be diploid or androgenetic; 39 of these were proved homozygous, indicating duplication of the male genome, whereas heterozygous origin by dispermy was likely in 13. The locus-specific minisatellite deoxyribonucleic acid probes were particularly useful for the identification of heterozygous complete hydatidiform moles. None of the patients with partial hydatidiform moles had development of a gestational trophoblastic tumor. No difference was detected in the frequency of requirement for chemotherapy between patients with homozygous or heterozygous complete hydatidiform moles. (AM J OBSTET GYNECOL 1991;164:1270-7.)

Key words: Hydatidiform mole, gestational trophoblastic tumor, genetics

Hydatidiform moles are recognized macroscopically and classified by histopathologic examination into two categories, partial and complete.[1]

Genetic studies have established that partial hydatidiform moles are usually triploid, having two paternal and one maternal set of chromosomes,[2] whereas complete hydatidiform moles are diploid and androgenetic, having two paternal chromosome sets.[3] The majority of complete moles are genetically homozygous, having arisen by duplication of a haploid sperm genome, whereas a minority arise by dispermy and are therefore heterozygous at some loci.[4]

In both partial and complete hydatidiform moles the mitochondrial deoxyribonucleic acid (DNA) is maternal in origin as in a normal conceptus.[4] We describe a prospective study carried out between 1978 and 1987 in which hydatidiform moles were classified according to pathologic features, ploidy, and genetic origin. Follow-up of the patients enabled us to relate the type of hydatidiform mole to the risk of development of a gestational trophoblastic tumor.

Patients and methods

Patients. Fresh tissue and, where possible, 10 ml of heparinized blood from the patient and her partner were collected at termination of pregnancy for a suspected hydatidiform mole.

Pathologic diagnosis. Two hundred forty-nine samples of tissue were collected from participating hospitals, examined macroscopically and histopathologically, and classified as nonmolar, partial hydatidiform mole, or complete hydatidiform mole.[1]

Determination of cell ploidy. Ploidy of molar tissue was examined in the early part of the study by cytogenetics[4] and later by distamycin/4′,6-diamidino-2-phenylindole staining of interphase nuclei.[4] Where ploidy had not been determined by these methods, flow cytometry of nuclei prepared from blocks of formalin-fixed, paraffin-embedded tissue was used.[5]

Genetic studies. Chromosomal and enzyme polymorphisms were examined as previously described.[2] For studies of restriction fragment length polymorphisms in molar and parental tissue, DNA was prepared by means of standard techniques and examined with Southern analysis. Hybridization was carried out with probes selected for Y-specific sequences and for unlinked sequences of DNA that showed a high degree of polymorphism (Table I).

Patient follow-up. Subsequent to the evacuation of the hydatidiform mole, the patients were monitored by estimation of human chorionic gonadotropin levels.[8] Thus it was possible to obtain details of follow-up.

Results

Pathology. Of the 249 samples, 201 were classified as hydatidiform mole (151 as complete and 48 as partial); two hydatidiform moles could not be classified because the samples were inadequate (Table II). An additional case of a tetraploid conceptus[9] classified as partial hydatidiform mole on a review of the pathologic results was included in the study.

Ploidy. Ploidy of the molar tissue is shown in Table II. Twenty-six of the 49 partial hydatidiform moles were examined cytogenetically. Twenty-three were regular triploids and one was a tetraploid. The other two cases had the karyotypes 71,XXY,+C,+C[2] and 70,XXY,+mar,[4] respectively. None of the 40 complete hydatidiform moles examined cytogenetically deviated from a regular diploid karyotype.

By means of flow cytometry, three hydatidiform moles, classified pathologically as complete hydatidiform moles, were found to be triploid. Two of these cases were reclassified as partial hydatidiform moles on examination of further pathologic material from the referring hospital. One case of complete hydatidiform mole appeared to have only a haploid DNA complement on flow cytometry. In pathologic sections from the block used for flow cytometry, no evidence of tissue degradation was seen. The partial hydatidiform mole that was diploid by flow cytometry was reviewed but a pathologic diagnosis of partial hydatidiform mole was sustained.

Genetics

Partial hydatidiform moles. The parental origins and sex chromosome complements are shown in Table III. The triploid cases of partial hydatidiform mole were classified according to whether an origin by dispermy was proved (15 cases) or possible (15 cases). Where dispermy was possible, other mechanisms of origin that were not excluded are indicated in Table III. In all cases but one the additional chromosome set could be shown to be paternal in origin. In this case an origin by digyny could not be excluded. The tetraploid, with

Classification	*No. of cases*	*Resolved spontaneously*	*Treatment required*
Hydatidiform mole	202	175	27 (13%)
Partial hydatidiform mole	51	51	0
Complete hydatidiform mole	149	122	27 (18%)
Homozygous complete hydatidiform mole	39	30	9 (23%)
Heterozygous complete hydatidiform mole	13	10	3 (23%)

a 92,XXXX karyotype, had three paternal and one maternal chromosome sets, the most likely mechanism of origin being fertilization of an egg by three sperm.[9] In the other tetraploid case DNA analysis showed an equal genetic contribution from both parents (Fig. 1).

DNA analysis of the diploid partial hydatidiform mole showed both a maternal and paternal contribution to the molar sample. However, with all informative probes the paternal contribution appeared to be present in excess, suggesting that there might be two different populations of diploid cells present in the molar sample.

Complete hydatidiform moles. Genetic studies of the triploid complete hydatidiform mole showed one maternal and two paternal contributions, the situation usually associated with the pathology of partial hydatidiform mole. Of the 19 complete hydatidiform moles in which ploidy was not determined, genetic analysis showed that six cases were androgenetic in origin by excluding a maternal contribution to the genome. The 105 diploid and/or androgenetic complete hydatidiform moles have been divided into those where genetic studies were uninformative, those in which heterozygosity for one or more loci was demonstrated (heterozygous), those in which at least five markers for which the father was heterozygous were found to be homozygous in the molar tissue (homozygous), and those in which fewer than five markers for which the male parent was heterozygous were homozygous in the complete hydatidiform mole (probably homozygous). Of those where genetic origin was certain, 13 (25%) were heterozygous and 39 (75%) were homozygous (Table IV). Of the 13 heterozygous complete hydatidiform moles, eight were male, four were female, and sex was not determined in one.

Follow-up studies. Among the total 202 patients in this series, 27 (13%) subsequently required chemotherapy for a gestational trophoblastic tumor (Table V). In all 51 patients with partial hydatidiform mole, resolution of the molar pregnancy was spontaneous. Among the 149 patients with complete hydatidiform mole, 18% required chemotherapy, and among the subset of those patients in whom a definite genetic di-

agnosis was obtained, 23% required chemotherapy. No difference was found between patients with homozygous and heterozygous complete hydatidiform mole as far as the risk for development of gestational trophoblastic tumor is concerned.

Patients who required treatment were classified into risk groups that determine their initial chemotherapy.[10] The three patients with heterozygous complete hydatidiform mole who required treatment were initially in the low-risk category. Among the 24 treated patients with homozygous complete hydatidiform mole, 17 were assigned to the low-risk category and 7 to the medium-risk category. Two of the patients with heterozygous complete hydatidiform mole and six of the 14 patients with a genetic diagnosis of probable or definite homozygous complete hydatidiform mole originally treated in the low-risk category changed drug schedules because they failed to respond. All patients except one, who died of pulmonary embolism, responded to chemotherapy, and no sequelae have been reported.

Comment

In this study we accepted samples whenever a diagnosis of hydatidiform mole had been suspected on clinical grounds, but in 48 cases the diagnosis was not sustained pathologically. Assignment to the partial or complete mole category was difficult with small samples, particularly in the case of partial hydatidiform moles, where some sections of the tissue may appear normal and others may have the features of complete hydatidiform mole. Two cases remained unclassified.

The only accurate way of determining the precise karyotype of molar tissue is by cytogenetics, which necessitates fresh tissue and a successful culture to obtain metaphase spreads. However, an assessment of ploidy can be made by other techniques. The introduction of flow cytometry has been a useful advance because the method can be applied to cells recovered from formalin-fixed, paraffin-embedded material. Most molar samples are contaminated with some maternal tissue, whcih appears as a diploid peak on flow cytometry.[5] In triploid partial hydatidiform moles this provides a control diploid population. In the case of diploid complete hydatidiform moles a smaller tetraploid peak, which represents dividing molar cells, helps confirm that some of the diploid tissue is molar. In tetraploid hydatidiform moles the maternal diploid population is smaller, and an octoploid population of dividing molar cells may be identified.

Genetic polymorphisms can also be used to determine ploidy. For example, if three alleles are shown to be present at a single locus, it is diagnostic of trisomy (Fig. 2, *a*). If only two alleles are identified but one is present at a higher dose than the other (Fig. 2, *b*), this can again be taken as evidence of the trisomic state. The identification of trisomy with several markers would suggest triploidy.

Cytogenetics, enzyme polymorphisms, and restriction fragment length polymorphisms (Fig. 2) have demonstrated that partial hydatidiform moles usually have two paternal contributions and one maternal contribution to the genome. Genetic fingerprinting can be used to identify parental DNA, but the relative contributions of each parent may be difficult to determine. Examination of locus-specific minisatellite polymorphisms that are unlikely to be shared by parents provides a more appropriate means of determining the parental contributions. Since these probes identify telomeric sequences[11] that are likely to have undergone recombination during meiosis, the precise origin of partial hydatidiform moles cannot be determined with these probes. Cytogenetics, where polymorphisms are usually centromeric, was the only technique with which we were able to prove dispermy as the mode of origin. Use of molecular genetic probes for centromeric regions would enable the origin of partial hydatidiform moles to be determined by DNA analysis.

If all triploid partial hydatidiform moles arise by dispermy, the expected ratio of XXX/XXY/XYY

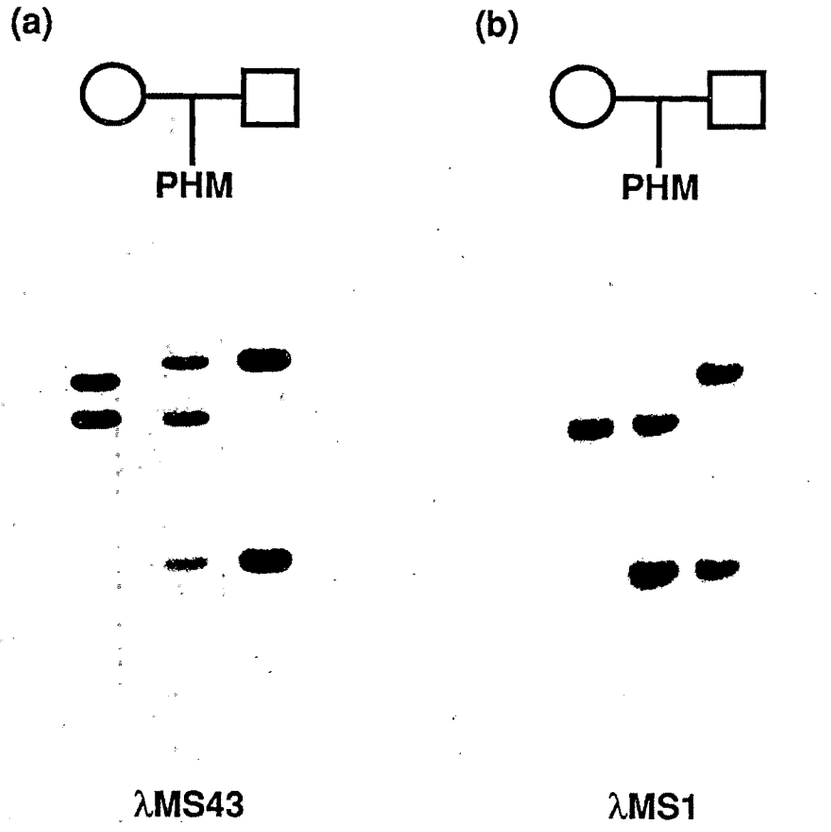

Fig. 2. a, Restriction fragment length polymorphisms in partial hydatidiform mole *(PHM)* showing two paternal and one maternal allele. **b,** Restriction fragment length polymorphisms in same partial hydatidiform mole showing greater paternal than maternal contribution.

would be 1:2:1, whereas in this series the ratio was 11:12:1. The deficiency of XYY has been observed among other series of triploid conceptions[12] and is assumed to be due to poor survival. The observed 1:1 ratio of XXX/XXY in this series might be explained if, where dispermy was not proved, triploidy was due to an error at patII producing XXX partial hydatidiform moles. However, a 1:1 ratio of XXX/XXY, rather than the 1:2 ratio expected, also was found among partial hydatidiform moles proved to arise by dispermy. It is possible that XXY partial hydatidiform moles are more subject to early loss by spontaneous abortion than are XXX partial hydatidiform moles.

The few previously described tetraploid conceptions with the pathologic features of partial hydatidiform mole had three paternal chromosome sets; therefore, like triploid partial hydatidiform moles, they have more paternal than maternal sets of chromosomes.[13] One tetraploid partial hydatidiform mole in this series apparently had an equal genomic contribution from each parent with the probes used (Fig. 1).

The case in this series in which the morphologic result was clearly partial hydatidiform mole and flow cytometry suggested diploidy appeared on molecular genetic studies to have a greater paternal contribution to the genome, compatible with triploid partial hydatidiform mole. These results suggest that two populations of cells might be present and that the conceptus was possibly hydatidiform mole with a nonmolar twin. In this case a cytogenetic study could have resolved the problem if cells from both populations had been established in tissue culture. Two sets of twins were identified unequivocally in our data.

In complete hydatidiform moles different polymorphic systems have been used to demonstrate androgenesis. The disadvantage of cytogenetics is that a result depends on successful tissue culture of molar cells. The best method of demonstrating a maternal exclusion is by use of locus-specific minisatellite probes (Figs. 3 and 4). The enzyme systems and the single-copy DNA sequences are not very polymorphic, and it may sometimes be difficult to distinguish between maternal contamination and a maternal contribution to the genome of the hydatidiform mole. With the polymorphisms identified by locus-specific minisatellite probes, maternal contamination can usually be identified as two bands

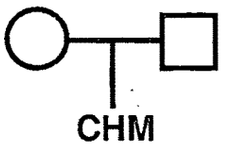

Fig. 3. Restriction fragment length polymorphisms in complete hydatidiform mole *(CHM)* showing only paternal contributions. It is homozygous for one of two paternal alleles.

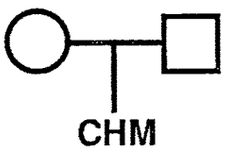

Fig. 4. Restriction fragment length polymorphisms in a complete hydatidiform mole *(CHM)* showing only paternal contributions. Genomes of male parent and complete hydatidiform mole are heterozygous.

weaker than those in the molar tissue, whereas a maternal contribution would generally give a single band.[7]

The Y chromosome or Y chromosome–specific sequences are useful for the identification of 46,XY heterozygous complete hydatidiform moles. To exclude the possibility of heterozygosity in 46,XX complete hydatidiform moles, it is also necessary to examine at least four autosomal loci for which the male parent is heterozygous. The probability that a complete hydatidiform mole with five homozygous markers has arisen by dispermy is then 1 in 32. Although DNA fingerprinting may demonstrate androgenesis, because of the complexity of the band patterns, it is not usually possible to distinguish with certainty between a homozygous and heterozygous complete hydatidiform mole with this technique. However, demonstration of two different paternal alleles with a locus-specific probe is proof of heterozygosity (Fig. 4).

The frequency of heterozygous complete hydatidiform moles in this series was 16%. Since there may be undetected heterozygous complete hydatidiform moles among the 46,XX cases tested for fewer than five informative markers, 16% is the minimum frequency of dispermic complete hydatidiform moles. A similar frequency of heterozygous complete hydatidiform moles has been observed in Japan.[14] The sex ratio 2:1 in the series XY/XX would be expected on the assumption that a YY conceptus is nonviable.

The patients in this series who required treatment for a gestational trophoblastic tumor were ascertained on the basis of human chorionic gonadotropin studies.[8] Since the diagnosis of gestational trophoblastic tumor was not based on pathologic results, the distinction between benign invasive mole and malignant choriocarcinoma could not be made. The molar pregnancy resolved spontaneously in all 51 patients with partial hydatidiform mole. This does not mean that there is no chance of a gestational trophoblastic tumor after partial hydatidiform mole, but it does confirm that the risk is low. Recently the incidence of therapeutic intervention after partial hydatidiform mole was estimated to be of the order of 1 in 200.[15] Unequivocable proof of the development of choriocarcinoma following pregnancy with partial hydatidiform mole is still lacking. It must

always be borne in mind that, although a gestational trophoblastic tumor is usually related to the immediately antecedent pregnancy, tumors can arise from earlier pregnancies (Fisher, RA. Unpublished data).

In this series there was no difference in the frequency with which patients with homozygous or heterozygous complete hydatidiform mole required treatment. This point is of interest because evidence from Japan suggests that patients with heterozygous complete hydatidiform mole have a much higher risk of development of gestational trophoblastic tumor than those with homozygous complete hydatidiform mole.[14] Although in our series we could not determine whether the gestational trophoblastic tumor was invasive mole or choriocarcinoma, we have shown by genetic studies of trophoblastic tumors that choriocarcinoma can develop from either a homozygous or heterozygous complete hydatidiform mole[16] (Fisher RA. Unpublished data).

As far as the response to treatment is concerned, we have not observed that the homozygosity or heterozygosity of a complete hydatidiform mole is a prognostic factor, since some of the patients in both categories required chemotherapy with more aggressive regimens than methotrexate and folinic acid.

Genetic studies in experimental animals have shown that the maternal and paternal genomes have different functions during the development of the embryo, because of differential gonadal imprinting.[17] In nuclear transplantation experiments in mice, only eggs with one male and one female pronucleus develop to term, indicating that both parental genomes are necessary for normal development.[17] In abnormal embryos with two male pronuclei, trophoblast developed relatively well whereas in those with two female pronuclei embryonic development was favored.[18]

This situation has a parallel in hydatidiform moles. In both complete and partial hydatidiform moles the presence of two paternal chromosome sets is associated with hyperplasia of the trophoblast; a triploid conceptus with one paternal and two maternal sets is not usually associated with a pathologic diagnosis of partial hydatidiform mole.[12] The diploid androgenetic complete hydatidiform mole shows a greater degree of trophoblastic hyperplasia, and an embryo does not develop. As in mice, androgenesis favors trophoblastic proliferation. In triploid partial hydatidiform mole the presence of a maternal contribution to the genome is associated with initiation of the development of an embryo, although it usually fails to develop properly.

The contribution of the paternal genome in relation to trophoblastic hyperplasia is also evident in the rare types of triploid and tetraploid hydatidiform moles.[13] Tetraploids without a maternal genome have the pathologic features of complete hydatidiform moles,[13] whereas if a maternal genome is present the pathologic results usually conform to partial hydatidiform mole. In cases of tetraploidy with the pathologic features of partial hydatidiform mole that apparently have equal genomic contributions from each parent, only some chromosomes have been examined. Thus it cannot be excluded that there are genetic regions, which are concerned with trophoblastic proliferation, where paternal alleles are present in excess. A similar situation occurs in patients with genetic disorders who, although having a normal diploid karyotype, have regions of the genome that are derived from only one parent, a condition termed *uniparental disomy*.[19] This could possibly also account for those rare cases where an apparently normal diploid conceptus is associated with molar pathologic results.[13]

The effect of genomic imprinting also applies to gestational trophoblastic tumor in that an androgenetic complete hydatidiform mole is associated with a greater risk of the development of gestational trophoblastic tumor than a normal conceptus, whereas in partial hydatidiform mole, which has one maternal and two paternal sets of chromosomes, the risk is intermediate. Thus both the pathologic features of hydatidiform mole and the risk of gestational trophoblastic tumor are related to the ratio of maternal to paternal genomes in the conceptus.[20]

We are grateful to the obstetricians who supplied us with tissues from their patients and to Prof. K.D. Bagshawe, Prof. R.H.J. Begent, Dr. E.S. Newlands, and Dr. G.J.S. Rustin for clinical information. We thank our colleagues, Dr. Sue Povey, S. Jeremiah, D. Sheppard, Clare Martin. Dr. M. Ormerod, and P. Imrie, for their collaboration, and Dr. C. Bishop. Dr. I. Boime, Dr. J.W.M. Hoppener, Prof. A.J. Jeffreys, Dr. L. Leinwand, Dr. L.-C. Tsui, and Dr. J. Wolfe for donating molecular probes. The probes, λMS1, λMS31, pλg3, and λMS43, are the subject of patent applications and commercial inquiries regarding these probes should be directed to Cellmark Diagnostics, Unit 8, Blacklands Way, Abingdon, Oxon United Kingdom OX14 1DY.

The effect of sterile water blocks on low back labor pain

Birgitta Trolle, MD, Margrethe Møller, MD, Hanne Kronborg, and Søren Thomsen, MD
Aalborg, Denmark

To evaluate the analgesic effect of intradermal sterile water blocks, 272 women in labor complaining of severe low back pain were randomly assigned to treatment with either sterile water or saline solution blocks. Pain intensity was assessed on a visual analog scale, before the blocks were given and again 1 and 2 hours later. The groups were equal with regard to age, parity, fetal size, progression of labor, and initial pain scoring. Pain scoring 1 and 2 hours after the blocks were given showed a significantly higher degree of analgesia in the sterile water group. No adverse effects were noted, and patient acceptability was high. (AM J OBSTET GYNECOL 1991;164:1277-81.)

Key words: Obstetric analgesia, low back labor pain, sterile water blocks

About one third of women in labor have severe, continuous, low back pain, and an additional number feel the pain of contractions primarily in the back.[1] To reduce this pain, a number of analgesic methods have been tried with varying success, i.e., transcutaneous nerve stimulation,[2,3] epicutaneous application of a local anesthetic agent,[4,5] and intracutaneous or subcutaneous infiltration of the skin with procaine hydrochloride (Novocain).[6,7]

Intradermal injection of small amounts of sterile water, called sterile water blocks, was reportedly effective against ureteral colic,[8] and in this article we present the result of a double-blind, randomized trial comparing the analgesic effects of intradermal sterile water blocks with those of isotonic saline solution blocks on low back labor pain.

Material and methods

Women in active labor complaining of severe low back pain were asked to participate and given detailed

Table I. Maternal characteristics for sterile water and groups

	Sterile water (n = 141)	*Saline solution (n = 131)*
Primiparous women (%)	70.2 75.6	
Gestational length (wk)	39.9 ± 1.6	39.7 ± 2.1
Maternal age (yr)	26.2 ± 5.1	25.9 ± 3.9
Cervical dilatation (cm)	4.73 ± 1.91	4.68 ± 1.91
Ruptured membranes (%)	59.6	52.7

Numbers are mean ± SD or percent. There are no significant differences.

Table II. Analgesic effects of sterile water and saline solution intradermal blocks on low back pain

	Sterile water	*Saline solution*	*p Value*
Immediately before blocks	83 (29-100) (*n* = 141)	81 (31-100) (*n* = 131)	0.23
After blocks			
1 hr	29.5 (0-100) (*n* = 132)	76 (0-100) (*n* = 121)	1×10^{-7}
2 hr	53.5 (0-100) (*n* = 100)	82 (1-100) (*n* = 99)	4.5×10^{-6}

Pain scoring (mean and range) and result of significance test before blocks and 1 and 2 hours later. As some women were delivered, groups diminished.

verbal and written information about the study. Those who accepted were asked to assess pain severity on a visual analog scale, a horizontal line 10 cm long without any markings, except the number *0* and the words *no pain* at the left end and the number *10* and *unbearable pain* at the right. This has proved to be a reliable method of measuring pain intensity.[9] The midwife in charge performed a vaginal examination, noting cervical dilatation. Sterile water and isotonic saline solution were provided in identical 1 ml ampules that had been randomly mixed and numbered. The midwife used the ampule next in number, giving the blocks by injecting about 0.1 ml intradermally at four different spots in the low back area, approximately corresponding to the borders of the sacrum.

The participants were asked whether they noted any analgesic effect from the blocks and, if so, the length of time before the effect began. Pain scoring and vaginal examination were repeated 1 and 2 hours after the injections if the woman had not yet been delivered. Apart from the blocks, the women were treated according to the usual principles of the department; they were offered nitrous oxide or pethidine if pain was severe. Any use of analgesics during the 3-hour period before block placement and the two subsequent hours was registered. Paracervical block and epidural anesthesia were not available. The water blocks could be given only once to each patient and only to those patients participating in the study.

Table III. Number of instrument-assisted deliveries specified in cesarean sections and vacuum extractions in sterile water and saline solution groups

	Sterile water (n = 141)	*Saline solution (n = 131)*	*p Value*
Cesarean section	6	15	<0.05
Vacuum extraction	22	13	NS
Total No. of instrument-assisted deliveries	28	28	NS

After delivery the patients were asked if they would request the same type of analgesia at subsequent delivery.

Clinical data of patients and infants and all complications during labor and delivery were registered, and a χ^2 test was used for comparison of frequencies. The scores on the visual analog scales were recorded as the distance in millimeters from point 0, and for each of the hourly intervals the groups were compared by a Mann-Whitney test. A p value of 0.05 was chosen as a significant level.

The study was approved by the local ethical committee.

Results

Two hundred seventy-two women received the blocks and completed the answer forms.

Sterile water blocks were given to 141 women and saline solution was given to 131 women. The groups were equal with regard to number of primiparous women, maternal age, and length of gestation and also with regard to mean cervical dilatation and number of patients who had ruptured membranes when the blocks were given (Table I).

Before they entered the study, 9.9% of the women in the sterile water group had already received pethidine in a standard dose of 75 mg intramuscularly, and 3.5% had received nitrous oxide. Corresponding figures for the saline solution group were 6.9% and 3.1%, respectively. In the sterile water group 126 (89.4%) of the women noted an analgesic effect of the blocks, compared with 59 (45%) in the saline solution group ($p < 0.0005$). The median number of minutes before the effect was apparent was 2 (range, 1 to 30) for both

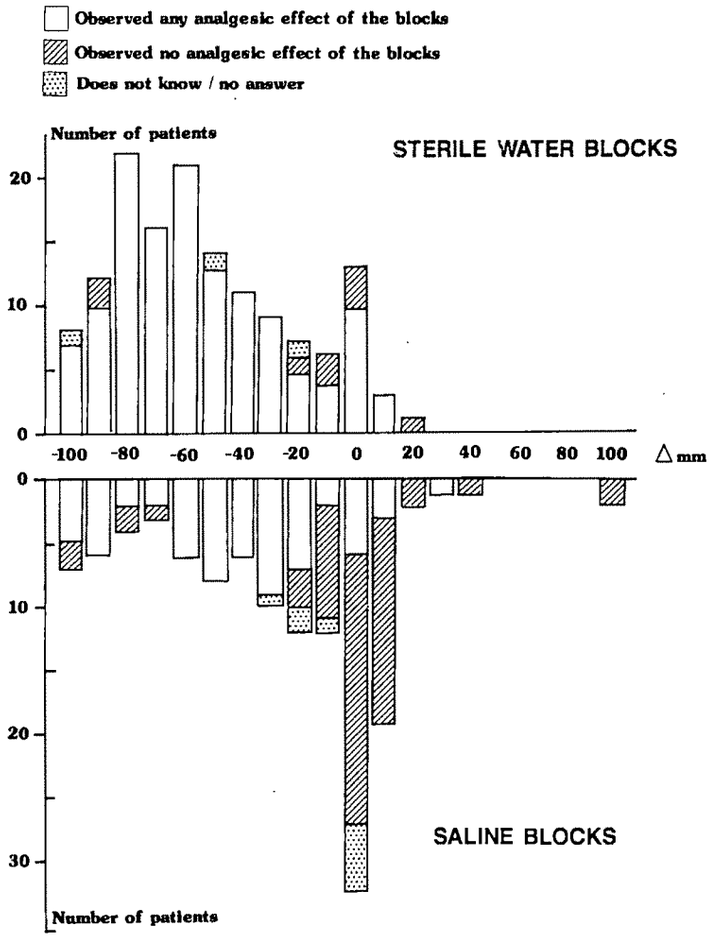

Fig. 1. Change in pain scoring after sterile water or saline solution blocks for low back labor pain, in relation to patients' answers to questions of any observed analgesia. Change in millimeters (Δ *mm*) is calculated as 1-hour scoring on the visual analog scale minus scoring before treatment.

groups. Initial pain scoring did not show any significant difference between the groups, but 1 and 2 hours after the blocks were given, there were highly significant differences (Table II).

During the 2-hour observation interval after the blocks were given, 6.4% of the patients in the sterile water group needed pethidine, and 12.8% received nitrous oxide, compared with 8.4% and 16%, respectively, in the saline solution group. These frequencies do not differ significantly.

Fig. 1 is a graphic illustration of the results. It shows the difference in analgesic effect between the groups but also demonstrates that even if no analgesia was noted, low back pain was at least constant and not increasing in spite of progressing labor. Except for the initial burning sensation, lasting for about 30 seconds, no local side effects were noted.

Progression of labor, expressed as time from application of the blocks until full cervical dilatation, was equal in the two groups (median, 2 hours; range, 0 to 11 hours). The second stage of labor had a median duration of 0.5 hours (range 0 to 2.25 hours) in both groups.

The rate of dystocia necessitating oxytocin stimulation was 39.7% in the saline solution group and 32.6% in the sterile water group. Although the rate of instrument-assisted delivery was similar in the two groups, the rate of cesarean section was significantly higher in the saline solution group (Table III). This was caused predominantly by a higher incidence of cephalopelvic disproportion and malposition of the occiput (Table IV). At vaginal delivery the rate of malposition of the occiput was 9.5% in the saline solution group and 5.2% in the sterile water group. The difference is not significant. There was no difference in average blood loss. Infant birth weight and Apgar scores also were equal.

A significantly greater proportion of the women in

Table IV. Indication for operative delivery in sterile water and saline solution groups

	Sterile water	*Saline solution*
Threat of asphyxia	11 (0)	5 (1)
Cephalopelvic disproportion	5 (5)	12 (10)
Lack of progression	4 (1)	0
Malposition of the occiput	1 (1)	10 (9)
Exhausted mother	11 (1)	8 (0)
Other	1 (1)	1 (1)

Numbers in parentheses indicate cesarean section. Some operations were performed for more than one indication. The total number of operative deliveries was 28 in each group.

Table V. Answer to question, "Will you request the same kind of analgesia if you are going to deliver again?" in sterile water and saline solution groups

	Sterile water (n = 141)	*Saline solution (n = 131)*
Yes	96	66
No	18	35
Undecided–no answer	27	30

$p < 0.005$, χ^2 test.

the sterile water group than in the saline solution group would request the same type of analgesia if they again had to undergo delivery ($p < 0.005$) (Table V).

Comment

Danish women do not expect childbirth to be painless. Epidural analgesia is available as a fulltime service in only a few centers. The use of paracervical block was largely abandoned after reports of fetal bradycardia, and pethidine is used mostly for women complaining of severe pain in early labor. Nitrous oxide is the most widely used analgesic, and pudendal block is offered to all women. Psychoprophylaxis is regarded as important, and most primigravid women attend free antenatal classes. Many primigravid, and most multigravid, women are delivered without any request for analgesia, and we find it reasonable to assume that the women who chose to participate in this study felt severe low back labor pain.

Pain impulses from the posterior part of the cervix and uterus are transmitted to the spinal cord segments T11-L1, and cutaneous branches from these segments supply the skin over the low back area.[10] This is probably the anatomic background of how pain originating in the cervix can be localized to the back. Low back pain occurs often in labor, especially in connection with an occipitoposterior presentation, where stretching of the posterior part of the lower uterine segment and cervix may be predominant. The hypotonic sterile water injected intradermally causes local irritation and thereby a strong sensory stimulation of the surrounding skin area for about 30 seconds. The analgesia induced by this stimulation may originate in midbrain centers,[11, 12] or be caused by "gate control" at the spinal level.[13, 14] Hyperstimulation of a skin area can affect perception of visceral pain, and it appears that the mechanism of referred pain can be reversed to produce referred analgesia.

Intradermal injection of isotonic saline solution is less painful than sterile water but not painless, and saline solution blocks could theoretically induce some degree of analgesia. To make the study double-blind some kind of injection in the low back area had to be used in the treatment of the control group. Comparing the blocks with any of the established methods of analgesia was abandoned for the same reason. These circumstances make it impossible to state the number of patients having only a placebo effect of the blocks.

A great number of women joined the project. A study of this size has a power of almost 90% in detecting a difference in proportions between the two groups of at least 15%.

The highly significant difference in pain intensity between the groups after the blocks were given is not reflected in the use of pethidine, which was similar in the two groups. The number of women receiving pethidine is small—smaller than the total number of women who did not have any analgesic effect of the blocks. It is not possible to make any conclusions.

We found it important to certify that the analgesic effect of the blocks was not connected with an impairment of labor, as this would only postpone pain. No such effect was noted. The incidence of dystocia and oxytocin infusion was high in both groups, but this was to be expected because only women with low back pain entered the study and low back pain commonly occurs with malrotation of the fetus.

There was no difference between the groups with regard to the rate of instrument-assisted delivery. However, the rate of cesarean section in the saline solution group was similar to the usual rate of cesarean section in our department (3000 deliveries per year), whereas the rate of cesarean section in the sterile water group was significantly lower (4.2% vs 11.4%). We have no definite explanation for this. The most frequent indications for cesarean section in the saline solution group were malposition of the occiput and cephalopelvic disproportion. In the Danish population the latter condition is usually relative, reflecting a fetal malrotation. It is not possible to determine if there was a primary difference between the study groups regarding fetal position or a higher rate of correction of fetal position in the sterile water group. Generally, the relation be-

tween labor pain and fetal position and the effect of analgesia on pelvic floor tone, cervical tension, contraction pattern, and fetal rotation are interesting and an evident subject for further studies.

Electronic fetal heart monitoring, auscultation, and neonatal outcome

Patricia H. Ellison, MD,[a] Mark Foster, MA,[a] Margaret Sheridan-Pereira, MD,[b] and Dermot MacDonald, MD[c]

Denver, Colorado, and Dublin, Ireland

In a large randomized, controlled study of fetal heart rate monitoring with either continuous electronic fetal heart monitoring or auscultation at specified intervals, only one pattern of deviation in the fetal heart rate correlated significantly with neonatal neurologic examinations at 0 to 48 hours and 72 hours to 1 week: late decelerations in stage 1 and in stage 2. Other variables from labor and delivery, specifically, duration of labor after hospital admission, failure of labor to progress, number of fetal scalp pH values, and presence of meconium were important predictors of neonatal outcome in the regression analyses. The fetal heart rate deviations did contribute significantly to the percent variance accounted for in the regression analyses with neonatal outcomes of Apgar scores at 1 and 5 minutes and serial neonatal neurologic examinations. (Am J Obstet Gynecol 1991;164:1281-9.)

Key words: Continuous electronic fetal heart monitoring, late decelerations, Apgar scores at 1 and 5 minutes, neonatal neurologic examination

Electronic fetal heart monitoring, when introduced in the 1960s and refined in subsequent years, brought hope that there could be a way to detect, in utero, an already compromised fetus, as well as a fetus in the process of deterioration, particularly during labor and delivery. In certain situations this technology has been fairly reliable, e.g., in the recognition of a dying fetus who previously might have been stillborn. It has been less reliable in the detection of fetuses with hypoxia-ischemia of the central nervous system and secondarily decreased regulation of heart rate.

In the majority of studies the relation was examined between fetal heart rate and the Apgar score, usually at 1 and 5 minutes. Very few studies have examined

the relation between fetal heart monitoring and neonatal neurologic examination obtained in a standardized manner.[1-9] However, the general course of most compromised newborns is improvement from the minute of birth through the hours or days until such examinations are performed, especially with expert resuscitation and neonatal care.

In this study we use the data from the Dublin randomized, controlled trial[5] to examine the relationships between a number of maternal and labor-and-delivery variables, including fetal heart rate and different fetal heart patterns, to several neonatal outcomes. The questions posed were: (1) Which specific fetal heart patterns are related to neonatal outcome as reflected in the Apgar scores at 1 and 5 minutes, the presence of convulsions, and the measures based on neurologic examination at 0 to 48 and 72 hours to 1 week? (2) Which other labor-and-delivery variables are related to these neurologic outcomes? (3) How much does each of these variables contribute to the prediction of outcome? (4) On which of these indicators do obstetricians base interventions, such as use of forceps or cesarean section?

All newborns in this study were examined by a physician before discharge. Approximately 1000 were examined neurologically by a research physician using a standardized method. These newborns constituted all those admitted to the special care baby unit, all those with any neurologic abnormality on routine examination, and all those of special concern to the nursing staff. Every effort was made to examine in a standardized manner all newborns at risk for or suspected to have neurologic abnormality. The subsamples available for various analyses differed in size. However, all subsamples were not only larger than those in most such studies but sufficiently large to consider that the results were likely to represent the population well.

Methods

The data in this study were those from the Dublin trial, a randomized, controlled study that compared the effectiveness of electronic fetal heart monitoring and auscultation in assessing the health of the fetus during labor and delivery.[5] There were 12,964 women involved in the study at the National Maternity Hospital in Dublin between March 1981 and April 1983. Data for 10,089 deliveries were sent to the University of Denver for analyses. Women who had heavily meconium-stained or markedly decreased amniotic fluid or who had fetuses with abnormal heart rates on admission were not enrolled. The women were randomly assigned to assessment by continuous electronic fetal heart monitoring or to intermittent monitoring by auscultation. Fetal scalp sampling was available to both sections.

Four subsamples were used in the results described in this article. The auscultation-only group was a random sample of all deliveries for which data were sent and in which only auscultation of the fetal heart was performed (n = 2362). The electronic fetal heart monitoring group, which was equal in number to the auscultation-only group, included all deliveries assigned to electronic fetal heart monitoring for which data were available for both stages 1 and 2 (n = 2362). The auscultation-plus-neurologic group, a random sample equal to that of those babies who had electronic fetal heart monitoring in stages 1 and 2 and a

Table IB. Mean Apgar scores and duration of labor

	Auscultation (n = 2362)	*Electronic fetal heart monitoring (n = 2362)*	*Auscultation plus neurologic examination (n = 135)*	*Electronic fetal heart monitoring plus neurologic examination (n = 135)*
1 min	8.8 ± 1.0	8.7 ± 1.0	7.6 ± 2.4	7.6 ± 2.1
5 min	9.1 ± 0.6	9.1 ± 0.6	8.7 ± 1.1	8.7 ± 1.2
Duration of labor (after entering hospital)	3.5 ± 2.6	4.2 ± 2.6	3.7 ± 2.8	4.9 ± 3.1

neurologic evaluation at 0 to 48 hours and 72 hours to 1 week, was from those deliveries that were monitored only by auscultation and in which the babies underwent a neurologic examination by the research physician at both 0 to 48 hours and 72 hours to 1 week (n = 135). The electronic fetal heart monitoring–plus-neurologic group, equal in number to the auscultation-plus-neurologic group, included those neonates whose mothers were assigned to electronic fetal heart monitoring, had such data during stages 1 and 2, and had both neurologic examinations by the research physician (n = 135). We wanted to compare samples of equal size and used random sampling to form the subsamples. In the regression analyses the sample sizes of each of these groups decreased slightly because of missing data.

A large number of maternal, fetal, and labor-and-delivery variables were recorded, including maternal age, parity, gravidity, gestational age of fetus, use of oxytocin or pethidine, length of time from admission to delivery, failure of labor to progress, delivery by cesarean section or forceps, and Apgar scores at 1 and 5 minutes.

The fetal heart tracings were interpreted by an obstetrician who had no knowledge about the mother, the other information about the labor and delivery, or the condition of the baby. The categories were marked bradycardia, late deceleration pattern, severe variable deceleration pattern, marked tachycardia, moderate tachycardia with reduced variability, moderate bradycardia with reduced variability, minimal variability, moderate variable decelerations, moderate tachycardia with normal variability, mild variable deceleration pattern, early deceleration pattern, reduced variability, moderate bradycardia with normal variability, acceleration pattern, normal baseline and variability, and unclassifiable (poor quality, labor too short, monitor disconnected, and not known—trace missing).

All newborns were examined physically and neurologically before discharge by a physician. Those newborns for whom there was concern about neurologic dysfunction by physician or nurse for any reason or who were admitted to the neonatal intensive care unit were examined by one physician using a comprehensive neonatal neurologic examination. This included individually scored items from the Dubowitz,[10] Prechtl,[11] and Brazelton[12] methods of evaluation, as well as items for gestational age scoring. The babies were examined at 0 to 48 hours, at 72 hours to 1 week, and at weekly intervals until discharge. The overall examination result was scored as normal, questionably abnormal, or abnormal. Data also were recorded about neonatal death, congenital abnormalities, and neonatal convulsions. The neurologic data were subsequently analyzed extensively and used to construct a neonatal neurologic assessment instrument with a total score and seven subscores.[13]

Frequencies were reviewed for all variables, as well as distributions and skews. Pearson product moment correlations and point biserial correlations (for dichotomous variables) were obtained and reviewed among all variables for each sample. Multiple regression analyses were obtained for different outcomes: Apgar scores at 1 and 5 minutes and neurologic examination at 0 to 48 hours and 72 hours to 1 week. The variables entered in the regression analyses for the two auscultation groups were confined to duration of labor, presence or absence of meconium, failure of labor to progress, use of oxytocin, number of fetal scalp samples, and any fetal heart rate abnormality. The regression analyses for the two electronic fetal heart monitoring groups were confined to the first five variables as noted above plus the ominous (marked bradycardia, late deceleration pattern, and severe variable deceleration pattern) and suspicious (marked tachycardia, moderate tachycardia with reduced variability, moderate bradycardia with reduced variability, minimal variability, and moderate variable decelerations) fetal heart patterns entered separately for stages 1 and 2. The ominous and suspicious rankings were determined by the obstetric classifications. The decision to select variables for entry in the regression analyses were based on review of the correlation matrices. Finally, regression analyses were obtained to determine those labor variables that accounted for obstetric intervention—use of forceps or cesarean section. The variables entered in the regression analyses were restricted to those described above for the four samples.

Normal baseline and variability	45.6	33.1	16.4	13.5
Unclassifiable	0	0	0	1.4

ples are shown in Table IA. Intervention by use of forceps is low, with the exception of the electronic fetal heart monitoring–plus–neurologic examination subsample. The rate of cesarean section is also low, particularly in comparison with that of American samples. The means and standard deviations for Apgar scores at 1 and 5 minutes and for the duration of labor after hospital entry are shown in Table IB. The 1- and 5-minute Apgar scores were somewhat lower and the standard deviations larger for the two subsamples with neurologic examination. The duration of labor was longest for the electronic fetal heart monitoring–plus–neurologic examination subsample.

The frequencies of fetal heart monitoring patterns are shown in Table II for the subset with electronic monitoring. The frequencies for the patterns that have been characterized as ominous are low, with the exception of marked bradycardia in stage 2 labor. The frequency of patterns that have been characterized as "nonreassuring" is high during stage 2 labor, especially for early deceleration. The frequency of normal baseline and variability decreases to only a small percentage of fetuses by stage 2. Thus the majority of patterns were described as "other than normal."

In Table IIIA the few correlations with significance are shown between those fetal heart patterns and outcomes. The most significant correlations were those between late decelerations (stage 1) and the development of convulsions and two neurologic examinations. There also were statistically significant correlations between late decelerations (stage 2) and the development of convulsions and two neonatal neurologic evaluations, but they were smaller. The correlations between presence of meconium, duration of labor, failure to progress, use of oxytocin, and number of scalp pH values and the several outcomes are shown in Table IIIB. The only significant correlation with the second neurologic evaluation is presence of meconium.

In Table IV the results are shown for the regression analyses with Apgar score at 1 minute as the dependent variable. In all the subsamples the percent variance accounted for ranged from 3.2 to 24.3. The heart rate abnormalities were significant in adding to the prediction in the auscultation, electronic fetal heart monitoring, and electronic fetal heart monitoring–plus–neurologic examination groups. However, larger contributions were made when specific patterns were used as in the electronic fetal heart monitoring and electronic fetal heart monitoring–plus–neurologic examination groups. The specific patterns combined to make the largest contribution in the electronic fetal heart monitoring–plus–neurologic examination group; those patterns were minimal variability (stage 1), marked bradycardia (stage 2), and late decelerations (stage 2). In the electronic fetal heart monitoring group, late decelerations (stage 2) was the most powerful predictor variable; in the electronic fetal heart monitoring–plus–neurologic examination group, marked bradycardia (stage 2) was the lead or most powerful predictive variable.

In Table V the results are shown for the regression analyses with Apgar score at 5 minutes as the dependent variable. In the auscultation and electronic fetal heart monitoring groups extremely small amounts of the variance were accounted for. In the subsamples evaluated neurologically, a larger percent of the vari-

ance was accounted for, and this percent was further increased with electronic fetal heart monitoring. Specific abnormal electronic fetal heart rate patterns contributed significantly to outcome in the electronic fetal heart monitoring and electronic fetal heart monitoring–plus–neurologic examination groups; in the electronic fetal heart monitoring group, severe variable decelerations (stage 1) and late decelerations (stage 2); in the electronic fetal heart monitoring–plus–neurologic examination group, marked bradycardia (stage 2).

Table VI shows the regression analyses with the total score for the neurologic examination at 0 to 48 hours and at 72 hours to 1 week as the dependent variables. The neurologic examinations are much better accounted for when the specific electronic fetal heart patterns were used. Late deceleration in stage 1 was the major contributor to the percent variance accounted for in both neurologic examinations. The second neurologic examination should be a better predictor of the neurologic outcome of the baby than either Apgar score or first neurologic examination.

Table VII shows the regression analyses with use of forceps as the dependent variable. The intervention use of forceps was better accounted for than any other process in our analyses. In short, the model by which physicians act was very well described. In each subsample failure to progress was the leading contributor. Abnormal fetal heart patterns, either as a group or with individual patterns, contributed significantly in each subsample but varied in their ranking.

Table VIII shows the regression analyses with cesarean section as the dependent variable. This intervention is less well accounted for than is the use of forceps. The physicians appeared to operate on a clinical basis, mainly on the basis of variables other than fetal heart patterns.

Comment

The data from the Dublin trial constitute a large sample, with particular attention to the description and categorization of electronic fetal heart monitoring patterns during both first and second stages of labor. The obstetric intervention rate with use of either cesarean section or forceps was very low. It may be reasonable to assume that the relationship between fetal heart monitoring, including particular electronic fetal heart patterns, and neonatal outcome would be larger than might be expected in other studies if the intervention cesarean section is assumed to decrease abnormal neonatal outcome.

It is much easier to account for the interventions of the obstetricians than for the outcomes of the babies. It is clear that forceps were used in labors that were failing to progress, with additional contributions from variables that might reflect fetal distress, including abnormal fetal heart patterns. However, the several specific electronic fetal heart monitoring patterns that were predictive of use of forceps may result simply from an association of deviance in fetal heart patterns with failure of labor to progress. Our results do not necessarily indicate that the obstetrician considered all of these patterns to be helpful in making the decision to use forceps. The uses of cesarean section and forceps were based more on failure of labor to progress than on the fetal heart patterns.

Few specific fetal heart patterns were significantly

associated with abnormal outcomes, either in the correlational analyses that used individual patterns (see Table IIIA) or in the regression analyses (Tables IV to VI), which included all ominous and suspicious patterns for stages 1 and 2 as defined by the obstetricians. We consider that Apgar scores and the neurologic evaluations represent quite different qualities about the neonate. Different configurations predict these different measures. The Apgar scores are probably broader measures registering different types of depression. Each improved across time: the Apgar score from 1 to 5 minutes and the neurologic evaluation from 0 to 48 hours to 72 hours to 1 week. Perhaps some of the confusion about the reliability of electronic fetal heart monitoring as a predictor of outcome is based on studies that used Apgar scores as a key outcome variable.

Electronic fetal heart monitoring plus neurologic examination			
Meconium	0.37	0.00	Multiple R = 0.47 Percent variance = 21.8

We consider neurologic evaluations at ages 0 to 48 hours and 72 hours to 1 week as better indicators of neurologic normality or abnormality than Apgar scores. The specific electronic fetal heart monitoring patterns of late decelerations (stage 1) and marked bradycardia (stage 2) do add significantly to the predictions to neurologic normality or abnormality (see Table VI). The percent variances accounted for are not large and perhaps not what the clinician might wish, but they indicate improvement from prediction that is based solely on other clinical variables.

In general, the Dublin trial perhaps has met criteria for excellence for randomized controlled trials better than most other electronic fetal heart monitoring[14] studies. Some have criticized the Dublin trial for the manner in which the fetal heart tracings were interpreted and the speed of the paper used in the electronic monitoring.[15] Systems have been proposed that incorporated accelerations, decelerations, and heart rate amplitude and variability in a single scoring.[16] Some categorizations in the Dublin trial did incorporate more than one variable, e.g., heart rate and variability. Only one categorization was permitted for each tracing. It is possible that another scoring system would modestly increase the percent variance accounted for. It is also possible that the use of trend analysis in contrast to pattern recognition for one or both stages of labor would increase the percent variance that was accounted for.

Another variable that was not scored with adequate distinction was the use of forceps. It would have been useful to distinguish between low forceps and mid forceps (high forceps reportedly were not used). That might have given more information about whether a modest increase in cesarean sections might have prevented the few forceps-related trauma cases (n = 3).

Fortunately, fetal conditions that are generally considered to be the most abnormal are very-low-frequency events. When there are no indicators of fetal stress, such as meconium, or no risk factors for fetal stress, such as use of oxytocin, prolonged labor, or failure to progress, then auscultation cannot be shown to be any less effective than electronic fetal heart monitoring. In this study, as in most others, auscultation was performed under a rigid protocol. However, when stress indicators appear, such as meconium, then specific, electronically monitored fetal heart patterns are additive in accounting for outcome.

We doubt that it is possible to increase more than modestly the accuracy of electronic fetal heart monitoring in predicting neurologic outcome by some combination of pattern analysis. Other variables add to the prediction, and they should be well heeded because there are so few variables that aid in making reasonable decisions. Furthermore, it is only in a small percentage of deliveries that the fetal heart patterns in combination with other variables can be used as justification for intervention. A technology that defines more than 40% of the heart rate patterns as deviant cannot possibly be accurate in predicting a very-low-frequency outcome such as neurologic abnormality. On the other hand, increased attention to the fetal heart rate and increased attention to the labor, as a result of the development of electronic fetal heart monitoring, may have significantly improved the outcome of labor and delivery.

Cost-effectiveness of prenatal testing for *Chlamydia trachomatis*

Mary D. Nettleman, MD,[a] * and Thomas A. Bell, MD, MPH[b] **

Iowa City, Iowa, and Seattle, Washington

We investigated the cost-effectiveness of strategies for screening pregnant women for *Chlamydia trachomatis*. Screening was not cost-effective unless certain conditions were met. Direct antigen testing of all pregnant women would be cost-effective if the test cost <$6.30 or the prevalence of infection exceeded 6%. However, the positive predictive value of the test was only 51%. Culturing was not cost-effective until the prevalence of infection exceeded 14.8%. If a direct antigen test cost <$3.90 or prevalence exceeded 8.7%, direct antigen testing of all women and using culture to confirm positive direct antigen tests would be cost-effective. If a direct antigen test cost $8.00 and culture cost $25.00, the excess cost of performing a direct antigen test in all women and confirming positive results with culture would be $2.09 per pregnant woman. Screening all pregnant women for chlamydia is not cost-effective, but the excess cost is modest when direct antigen tests are used. (AM J OBSTET GYNECOL 1991;164:1289-94.)

Diagnostic tests for detection of *Chlamydia trachomatis* have been shown to be cost-effective in nonpregnant women attending sexually transmitted diseases clinics who are not candidates for empiric therapy and in asymptomatic women at moderate risk for infection.[1, 2] The cost-effectiveness of screening pregnant women is more complicated because treatment options are limited, the sequelae of infection are more varied, and both mother and infant need therapy when a pregnant

Table I. Costs of conjunctivitis and outpatient pneumonia

Cost of conjunctivitis	
Physician visit	$ 35
Bacterial isolation, smear	$ 30
Direct antigen test	$ 8
Erythromycin	$ 7
Empiric treatment of mother	$ 10
Empiric treatment of male partner	$ 10
TOTAL	$100
Cost of outpatient pneumonia	
Two physician visits	$ 70
Direct antigen test	$ 8
Bacterial isolation, smear	$ 30
Respiratory syncytial virus test	$ 26
Blood profile	$ 19
Bordetella pertussis test	$ 20
One chest radiograph	$ 72
Erythromycin	$ 7
Empiric treatment of mother	$ 10
Empiric treatment of male partner	$ 10
TOTAL	$272

Table II. Cost of uncured chlamydial infection

Addverse outcome	*Cost*	*Probability*	*Weighted cost**
Neonatal conjunctivitis	$ 100	0.1900†	$19.00
Outpatient neonatal pneumonia	$ 272	0.0855†	$23.28
Inpatient neonatal pneumonia	$2500	0.0285†	$71.25
Outpatient salpingitis	$ 196	0.0840	$16.46
Inpatient salpingitis	$3071	0.0160	$49.14
Subsequent ectopic pregnancy	$4115	0.0070	$28.81
Outpatient epididymitis	$ 50	0.0400	$ 2.00
Inpatient epididymitis	$1876	0.0040	$ 7.50
TOTAL			$217.44

*Weighted cost is the cost of the adverse outcome multiplied by the probability of its occurrence.

†The probability of neonatal infections is adjusted for the proportion of women undergoing cesarean section.

woman is infected. We performed a decision analysis to determine the cost-effectiveness of various strategies for screening pregnant women.

Material and methods

Assumptions. Costs were based on local charges except where indicated. Although the terms *cost* and *charge* are used interchangeably, all monetary values were charges, which were chosen because they included the additional burden on third-party payers and the costs of health care resulting from disease or from screening programs. Potential complications of a chlamydial infection in a pregnant woman included conjunctivitis and pneumonia in her infant, epididymitis in her sexual partner, and her own risks of postpartum endometritis or salpingitis and ectopic pregnancy. The mean cost of neonatal conjunctivitis was assumed to be $100, and that of pneumonia caused by *C. trachomatis* in an infant outpatient, $272 (Table I). The cost of pneumonia in an inpatient was estimated to be $2500 from third-party fixed reimbursement for "viral pneumonia." A review of seven cases at the University of Iowa and five cases at the University of Washington yielded mean charges of $2465 and $4358, respectively, for *C. trachomatis* pneumonia in an inpatient. Therefore the effect of increasing the cost of pneumonia above $2500 was investigated by sensitivity analysis.

The costs of epididymitis were assumed to be $50 for outpatient therapy and $1876 for inpatient therapy.[3] The costs of outpatient and inpatient therapy for endometritis-salpingitis were $196 and $3071, respectively.[4] The cost of an ectopic pregnancy was $4115.[3,5] Adverse outcomes were assumed to occur in the first 2 years after an uncured infection; thus costs were not discounted.

The prevalence of chlamydial infection in pregnant women in the United States is approximately 5%.[6] Probabilities of complications were derived from the literature. The probabilities of conjunctivitis and pneumonia in infants born to infected mothers have been reported to be as high as 50% and 20%, respectively.[6-9] However, recent studies[10-12] have suggested that the occurrence of both events may be lower. We assumed that 25% of infants born to infected mothers developed conjunctivitis; 15% were assumed to develop pneumonia,[10,12] 75% of whom would need only outpatient therapy.[11] Twenty-four percent of women were assumed to have a cesarean delivery[13]; only vaginal births were assumed to result in neonatal infection.

Women who were not cured before delivery were assumed to have a 10% risk of postpartum endometritis-salpingitis,[14] with 16% of these cases necessitating hospitalization.[4] Seven percent of women in whom salpingitis developed were assumed to experience a subsequent ectopic pregnancy.[15,16] Each infected woman was assumed to have one infected partner. Male partners were assumed to remain untreated unless the woman were identified as infected or the man developed epididymitis. Approximately 4% of infected men were assumed to have epididymitis, 10% of whom required hospitalization.[3,17,18] The total mean cost of an uncured chlamydial infection in a woman was $217.44 (Table II).

Salpingitis leads to infertility in approximately 21% of nonpregnant women,[17,19] and the cost of an evaluation for infertility is approximately $2500.[5] The probability of infertility and the probability that women who have already been delivered of a child will seek evaluation for infertility have not been determined. Therefore infertility was not included in the analysis but was considered during sensitivity analysis.

The cost of screening included the costs of the tests, therapy if tests were positive, the side effects of therapy,

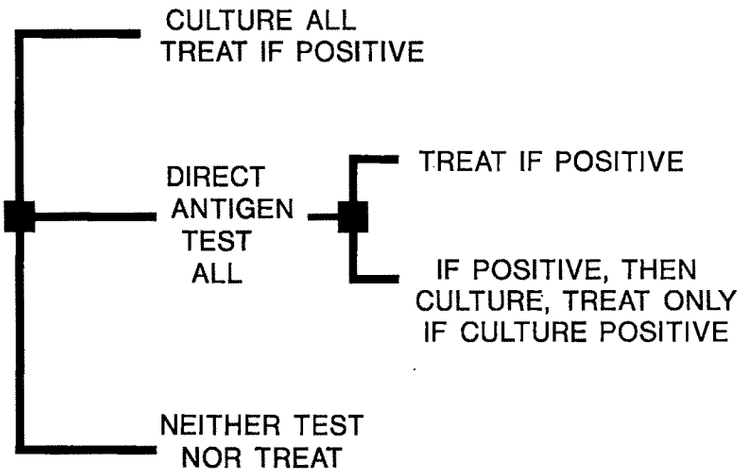

Fig. 1. Decision tree describing alternative screening strategies.

and empiric therapy of one male partner. The cost of a rapid direct antigen test was assumed to be $8, and the cost of treating a pregnant woman with erythromycin for 7 days was $10. Severe nausea and vomiting were assumed to require a visit to a physician at a cost of $35. Each woman whose test result was positive for *C. trachomatis* was assumed to have one sexual partner requiring empiric therapy ($10). We assumed that 3.3% of pregnant women would have severe nausea and vomiting from erythromycin and would not be cured.[11] For women who tolerated the medication, 92% would be cured with a single course of erythromycin.[11] Tests of cure after a course of therapy are not routinely recommended and were not included but were investigated during sensitivity analysis.[20]

Additional physician costs for examination were not added to the cost of routine screening because pelvic examination is routine in prenatal care. We assumed, however, that diagnosis of *C. trachomatis* conjunctivitis or pneumonia in an infant would prompt empiric therapy of the mother and one male partner.

The sensitivity of culture has been determined by comparing a single cervical specimen to multiple samples.[21,22] However, diagnostic tests for *C. trachomatis* are more sensitive in pregnant than in nonpregnant women.[23] Therefore we assumed that a single cell culture performed on a cervical swab had a sensitivity of 82% and a specificity of 100%.[23] A direct antigen test performed on a cervical swab was assumed to be 95% as sensitive and 96% as specific as culture.[23-25]

The analysis included only direct costs and excluded those related to transportation, emotional suffering, and time lost from work. We assumed that complications of *C. trachomatis* in infants would occur while women were still on maternity leave and that no wages would be lost. This may underestimate lost wages as a result of infant pneumonia, which is usually diagnosed after 6 weeks of age.[26] Approximately half of mothers with children under age 3 work, with a median income of $284 per week.[27] Sensitivity analysis was performed to determine if the addition of indirect costs to the cost of uncured infections affected the outcome of the analysis.

The effectiveness of a strategy was measured on a utility scale that ranged from 0 to 1, with 0 indicating the presence of uncured *C. trachomatis* in a pregnant woman and 1, the absence of *C. trachomatis* infection. Cost-effectiveness was defined as the total cost of a strategy divided by its effectiveness score (see Appendix).[1]

The following strategies were evaluated: (1) Neither test nor treat; (2) culture all pregnant women and treat if culture positive; (3) perform a direct antigen test in all women and treat if positive; (4) perform a direct antigen test in all women, confirm positive tests with culture, and treat only if the culture is positive (Fig. 1).

Results

Decision analysis. The most cost-effective strategy was neither to test nor to treat women for *C. trachomatis* (Table III). Testing all women with a direct antigen test was slightly less cost-effective, and testing all women with culture was least cost-effective. The strategy of testing all women with a direct antigen test and confirming positive results with culture had an intermediate cost-effectiveness value.

Detection of infection by culture had a specificity and positive predictive value of 100%. The positive predictive value of a direct antigen test used for this low-prevalence population was 51%, although the negative predictive value was high (Table III).

Cultures and direct antigen tests would detect 82% and 78% of all *C. trachomatis*, respectively. Confirmation

Table III. Cost-effectiveness and predictive values

Strategy	*Cost-effectiveness value*	*Positive predictive value*	*Negative predictive value*
Neither test nor treat	$11.77		
Direct antigen test all	$13.17	0.51	0.99
Culture all	$29.20	1.00	0.99
Culture only if direct antigen test is positive	$15.63	1.00	0.98

Table IV. Sensitivity analysis: breakpoints at which the three testing strategies become more cost-effective than not testing

	Direct antigen test all	*Direct test with culture confirmation*	*Culture all*
Cost of direct test	<$6.30	<$3.90	NA
Cost of culture	NA	Never	<$7.50
Infection prevalence	>6.1%	>8.7%	>14.8%
Cost of uncured infection	>$264	>$355	>$674
Probability of infant pneumonia	>22%	>36%	>87%
Probability of salpingitis in an untreated woman	>15%	>24%	>58%
Cost of outpatient pneumonia	>$815	>$1870	>$5700
Cost of inpatient pneumonia	>$4100	>$7300	>$18500

NA, Not applicable; *Never,* strategy is never more cost-effective than not testing at any value of the variable.

of positive direct antigen tests by culture would detect 64% of infections. For simplicity, the latter case assumes that the two tests are independent.

In 1988 there were approximately 3,941,000 births in the United States.[28] If each birth resulted from a single pregnancy, the national cost of screening all women with a direct antigen test would be approximately $8 million more than the cost of neither testing nor treating, representing an excess cost of $2.09 per pregnancy. If culture were performed in all pregnant women, $71 million in excess costs would be incurred ($17.94 per pregnancy). Finally, if direct antigen tests were performed in all pregnant women and positive results were confirmed with culture, the nation would incur $17 million in excess costs ($4.42 per pregnancy).

Sensitivity analysis. Sensitivity analysis was performed by varying each assumption over a range of possible values. The policy of testing and treating was less cost-effective than neither testing nor treating, unless certain conditions were satisfied. For example, if the cost of the direct antigen test were <$6.30 or the prevalence of infection in pregnant women were >6.1%, routine screening with the direct antigen test would be more cost-effective than neither testing nor treating (Table IV). Similarly, if the cost of the direct antigen test were <$3.90 or the prevalence of infection were >8.7%, using culture to confirm the direct antigen test would be more cost-effective than neither testing nor treating. Even using culture to test all women would be cost-effective if the prevalence of infection exceeded 14.8% or the cost per test fell below $7.50. Strategies involving the direct antigen test became cost-effective if the incidence of postpartum endometritis-salpingitis, neonatal pneumonia, or hospitalization for an infant with pneumonia were higher than we originally assumed. Specifically, changes that raised the mean cost of an uncured infection above $264, such as the addition of indirect costs, would make the use of the direct antigen test in all pregnant women cost-effective. For example, if the probability of pneumonia in the infant of an untreated, infected pregnant woman were >22% or the probability of conjunctivitis were >66%, direct antigen testing would become cost-effective.

If the cost of a test of cure had been included and 92% of women with failure of initial therapy were cured by a second course of erythromycin, the strategy of neither testing nor treating would remain the most cost-effective. The cesarean section rate did not affect the outcome of the analysis when allowed to range between 0% and 50%. The cure rate itself and the cost of treatment had no effect on the order of the strategies.

In addition, the sensitivity of culture did not affect the outcome of the analysis, even if it were assumed to be 100%. If culture-negative infected women were assumed to be so mildly infected as to have no complications, culture would remain less cost-effective than not testing. If indirect costs had been added and included 5 days off work for 50% of mothers whose children acquired pneumonia, direct antigen testing would be more cost-effective than neither testing nor treating.

The addition of costs for infertility did not affect the outcome of the analysis. Neither testing nor treating remained the most cost-effective strategy even if 21% of women with endometritis-salpingitis became infertile and 50% of them sought medical evaluation.

Comment

Testing pregnant women for diseases that can be transmitted transplacentally or perinatally is an important part of obstetric care. The advent of available, simple, and inexpensive screening tests has increased the possibility of routine prenatal screening for *C. trachomatis*.

Our analysis showed testing all pregnant women for *C. trachomatis* became cost-effective under certain conditions. If uniformly available for a charge of <$6.30 or with a population prevalence only 20% greater than what we assumed, routine screening with a direct antigen test would be more cost-effective than the current strategy of neither testing nor treating. If testing could be limited to subpopulations of women at moderately increased risk, direct antigen testing would become cost-effective. However, it is important for clinicians to realize that the positive predictive value of a direct antigen test in this population is only 51%. Thus half of women with positive tests, approximately 150,000 per year, would be treated unnecessarily. Conjugal relationships might be irreparably damaged from false-positive diagnoses. To minimize this damage, it would be important to interpret a positive direct antigen test only as an indication of increased probability of *C. trachomatis*, not as definitive evidence of infection.

Recent reports[29] indicate that the specificity of direct antigen testing may improve if all specimens are referred to central laboratories. Thus quality control may minimize false-positive diagnoses. In addition, bulk purchasing of direct antigen tests has lowered the cost per test to $4 in some instances. Such a test would be highly cost-effective.

To eliminate false-positive diagnoses, it would be cost-effective to use culture to confirm positive direct antigen test results if the charge for a direct antigen test were <$3.90 and the cost per culture were $25. If the cost of a direct antigen test remained at $8, $4.42 in excess charges would be incurred per pregnancy. More infected women would be missed by this strategy, but no uninfected women would receive treatment.

If culture were used to test all pregnant women, false-positive results would be eliminated and the maximum number of infected women would be identified for treatment. However, culture was not a cost-effective screening tool, and the charge for culture cannot yet be reduced to <$7.50.

When limited financial resources are available, decision analysis may guide providers to use strategies that maximize outcomes or minimize costs. However, an individual health care provider may choose a strategy that is not cost-effective, especially if the provider or patient does not have limited funds. Thus a physician may choose to culture out of concern for a patient's health and because the test has a high sensitivity, specificity, and positive predictive value. If all physicians adopted this strategy in caring for pregnant women, the cost of health care would increase by $17.94 per pregnancy.

Eradication of infection with *C. trachomatis* may have other benefits that are still under investigation. For example, infection has been linked to prematurity.[30,31] In addition, neonatal infection with *C. trachomatis* has been linked to chronic respiratory disease.[32,33] If either association is significant enough to increase the cost of uncured infection to >$264, then direct antigen testing would become cost-effective.

In summary, screening all pregnant women for infection with *C. trachomatis* would not result in a direct cost savings unless complications of uncured infection are shown to occur more frequently than assumed. However, the excess costs per pregnancy for either direct antigen testing or direct antigen testing with culture confirmation are modest and are justified by the morbidity of maternal and infant infection with *C. trachomatis*.

Appendix: Sample calculations

Cost-effectiveness. The cost-effectiveness of a strategy was defined as its total cost divided by its total utility score.[1, 32] For example, if no pregnant women were tested for infection with *C. trachomatis,* the total cost of the strategy would be derived from the cost of complications of untreated infection ($217.44, Table II). Because 5% of women were assumed to be infected, the total cost per patient would be:

$$(\$217.44 \cdot 0.05) = \$10.87$$

Patients who were not infected would receive a utility score of 1. Patients who were infected would not be tested or identified and would receive a utility score of 0. Thus the utility score per patient would be:

$$(0 \cdot 0.05) + (1 \cdot 0.95) = 0.95$$

The cost-effectiveness value for this strategy would be:

$$\$10.87/0.95 = \$11.44$$

Note that better strategies with lower costs or higher utilities will have lower cost-effectiveness values. For strategies involving testing, the costs of the tests and treatment and the cure rate as a result of treatment are included.

Predictive value. Positive predictive value is defined as the probability of disease given a positive test. Thus the positive predictive value of direct antigen testing is the probability of true infection in a woman with a positive test. It may be calculated by dividing the number of true-positive results by the total number of positive results.[32]

For a direct antigen test with a sensitivity of 78% and specificity of 96% in a population with a 5% prevalence of infection, the proportion of results that would be true positive is:

$$\text{True positive} = \text{Sensitivity} \cdot \text{Prevalence} = 0.78 \cdot 0.05 = 0.039$$

Thus 3.9% of all women would have both a positive test and true infection. Note that only the population of truly infected women, 5% of the total population, may have true-positive results.

False-positive results occur when the test is positive but disease is not present. This is a failure in the specificity of the test. In the current example 95% of the population does not have disease and the number of false-positive results is:

$$\text{False positive} = (1 - \text{Specificity}) \cdot (1 - \text{Prevalence}) = 0.04 \cdot 0.95 = 0.038$$

Thus 3.8% of all women would be uninfected and would have a positive test.

The positive predictive value is:

$$\text{Positive predictive value} = \text{True positive}/(\text{True positive} + \text{False positive}) = 0.039/(0.039 + 0.038) = 0.51$$

Thus 51% of women with positive test results will truly be infected. Conversely, 49% of women with positive test results will not be infected and will be treated unnecessarily.

Intraamniotic detection of *Chlamydia trachomatis* deoxyribonucleic acid sequences by polymerase chain reaction

Chia C. Pao, PhD,[a] Shu-Min Kao, BS,[a] Han-Chow Wang, MD,[b] and Cagge C. Lee, MD[c]
Taipei, Taiwan, Republic of China

The presence of *Chlamydia trachomatis* in cervicovaginal cells and amniotic fluid of pregnant women was examined by culture and by polymerase chain reaction deoxyribonucleic acid amplification methods. Chlamydial deoxyribonucleic acid sequences were found in nine of 31 (29.0%) cervicovaginal cell specimens, five of which also were positive by culture method. Amniotic fluid specimens from two of the nine (22.2%) cervicovaginal chlamydial deoxyribonucleic acid–positive women and none from the remaining 22 cervicovaginal chlamydial deoxyribonucleic acid–negative women were found to contain chlamydial deoxyribonucleic acid. The results underscore the significance and frequency of intraamniotic chlamydial infection in women with urogenital chlamydial infections. (AM J OBSTET GYNECOL 1991;164: 1295-9.)

Key words: *Chlamydia trachomatis,* intraamniotic infection, polymerase chain reaction

Infection with *Chlamydia trachomatis* is the most common sexually transmitted disease in many parts of the world today.[1] In women, *C. trachomatis* may cause cervicitis and urethral syndrome in the lower urogenital tract and endometritis and salpingitis in the upper urogenital tract. These infections also can lead to sterility[2] and other complications during pregnancy.[3, 4]

Detection of *C. trachomatis* is very important in both diagnosis and treatment of chlamydial infection because a substantial proportion of women infected with *C. trachomatis* are asymptomatic. A diagnostic method that is more sensitive than the currently available culture and immunologic assays is needed to detect many asymptomatic and subclinical chlamydial infections. Deoxyribonucleic acid (DNA) hybridization has made it possible for early detection of chlamydial DNA in clinical specimens from both healthy individuals and infertile patients.[5, 6] The advent of polymerase chain reaction has provided us with a rapid and direct method that can amplify extremely small quantities of DNA, facilitating subsequent detection by conventional methods such as the DNA hybridization method.[7] Polymerase chain reaction has been used successfully in the detection of many microorganisms and we have reported its use in the identification of human cytomegalovirus, human papillomavirus, and *Mycobacterium tuberculosis*[8-10] in clinical specimens.

In this text we report the results of our studies on the detection of *C. trachomatis* DNA sequences by the enzymatic amplification technique, which suggests that *C. trachomatis* DNA sequences can be found in the amniotic fluid of a substantial proportion of women with urogenital chlamydial infection.

Material and methods

Source of specimens. Amniotic fluid was obtained by amniocentesis from 31 consecutive pregnant women who underwent the procedure for the purpose of genetic consultation. Cervicovaginal cells were collected from these patients by washing the cervix with 2 to 4 ml of phosphate buffer (20 mmol/L, pH 7.0) containing sucrose (200 mmol/L), bovine serum (5%), streptomycin (50 μg/ml), vancomycin (100 μg/ml), and nystatin (25 U/ml). None of the patients had known or diagnosed cervicovaginal chlamydial infection at the time of amniocentesis or cervicovaginal cell sampling. The average age of the patients was 25.2 years. Seven and nine of the women were pregnant for the first and second time, respectively, and the remainder were pregnant for the third time or more. Informed consents were obtained from all patients.

Chlamydial culture. Culture for chlamydia was performed with cycloheximide-treated McCoy cell monolayers described in detail elsewhere.[11] The reference strain of *C. trachomatis* (ATCC-VR 885) was obtained from American Type Culture Collection (Rockville, Md.).

Polymerase chain reaction. Cervicovaginal cells and cells in 1 ml of amniotic fluid were collected

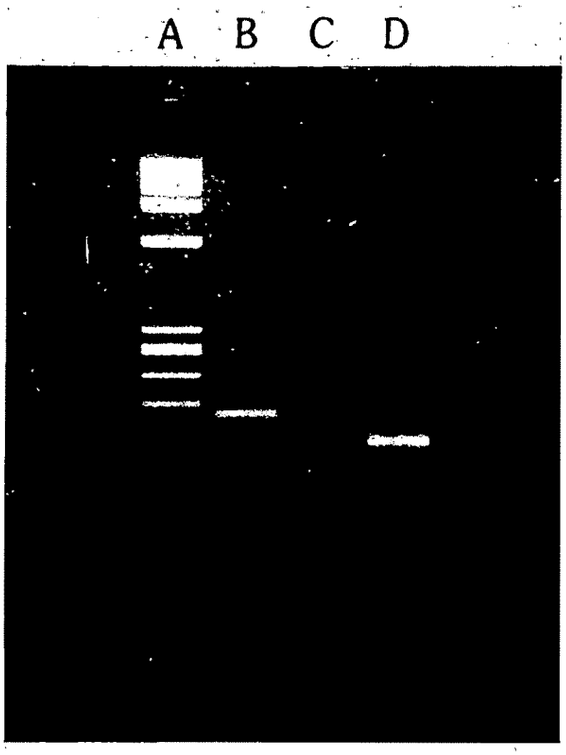

Fig. 1. Agarose gel electrophoresis of *C. trachomatis* DNA amplified with polymerase chain reaction. *Lane A* is restriction endonuclease *Hae* III–digested Phi-X 174 phage DNA used as size standards; the sizes of the DNA bands are (from top to bottom) 1353, 1078, 872, 603, 310, 281, 271, 234, 194, 118, and 72 base pairs. *Lane B* shows amplification of DNA prepared from ATCC reference strain of chlamydia with 182 base pair DNA band indicating *C. trachomatis* DNA positivity. *Lane C* is negative control in which 50 ng of human DNA was amplified. *Lane D* is DNA shown in *lane B* after restriction endonuclease *Hha* I treatment. The 32 base pair DNA in *lane D* is too short to be visible clearly.

by centrifugation and washed in phosphate-buffered saline solution twice before they were resuspended in 250 μl of Tris hydrochloride buffer (10 mmol/L, pH 8.3) containing potassium chloride (50 mmol/L), magnesium chloride (2.5 mmol/L), gelatin (0.1 mg/ml), NP40 (0.45%), Tween 20 (0.45%), and proteinase K (500 μg/ml). The mixture was kept at 56° C for 1 hour, followed by 10 minutes at 95° C to inactivate the proteinase K. Ten microliters of the treated mixture was then used directly for the polymerase chain reaction. The nucleotide sequences of the two primers are (from the 5′-end to the 3′-end) AACTCAAAACCCTCTCATTCTCAA and AAACGTTCGTCCCAGGAAGAAGCC, and they cover a 182-base portion of a gene code for a major outer membrane protein of *C. trachomatis*.[12] The polymerase chain reaction procedures were those we have described earlier[9] with these modifications. Briefly, the 100 μl reaction mixture contains 10 mmol/L Tris hydrochloride buffer, pH 8.3; 50 mmol/L potassium chloride; 1.5 mmol/L magnesium chloride; 0.01% gelatin; 20 pmol each of the two primers; 2.5 nmol each of the four deoxyribonucleoside triphosphates; 1 unit of *Taq* DNA polymerase (Perkin-Elmer Cetus, Norwalk, Conn.), and DNA from specimen, positive controls, or negative controls (see below). The temperature of the reaction mixture was first raised to 94° C for 20 seconds to denature the DNA, then brought down to 63° C for another 20 seconds to allow annealing of primers to putative target DNA sequences. The reaction mixture was then raised to 72° C for 1 minute to extend the DNA chain. This whole process was repeatd 32 times with a 10-minute incubation at 72° C at the end.

Establishment of *C. trachomatis* DNA positivity. Southern blot hybridization was performed on all polymerase chain reactions to enhance both the sensitivity and the specificity of the amplification process and to establish the *C. trachomatis* DNA positivity. For the Southern blot hybridization, 10 μl of amplified reaction mixture was fractionated by 2% agarose gel electrophoresis and transferred to nitrocellulose membrane filters. An internal oligonucleotide (AACATAAAAAGATATACAAAAATGGCTCTCTGCTTTATCG) derived from nucleotide sequences located inside the two primers on the *C. trachomatis* genome was labeled at its 5′-end with phosphorus 32 by polynucleotide kinase to 1 to 5×10^6 counts per minute per picomole and used as probe. Procedures for Southern blot hybridization have been described previously by others[13] and were modified for oligonucleotide probes as follows: After hybridization, the filters were washed sequentially in 2× SSC (1× SSC is 0.15 mol/L sodium chloride and 0.015 mol/L sodium citrate) and 0.5% sodium dodecyl sulfate twice for 10 minutes each at room temperature, then in 0.1× SSC and 0.5% sodium dodecyl sulfate three times for 20 minutes each at 55° C. Restriction endonucleases were purchased from either Boehringer Mannheim (Mannheim, Federal Republic of Germany) or BRL (Gaithersburg, Md.) and used according to manufacturers' recommendations.

Precautions against contamination and false-positive results in polymerase chain reaction. Because of the extraordinary amplification power of the polymerase chain reaction technique, a number of precautionary measures were taken to minimize any possible contamination during sampling and subsequent processing. Gloves were always worn during sampling and processing of specimens. Areas of skin were extensively cleaned before amniocentesis. Special steps also were taken to minimize sample-to-sample contamination and polymerase chain reaction product carryover to avoid false-positive results. These steps include aliquoting of

all reagents, physical separation of products and reagents before and after polymerase chain reaction, and meticulous laboratory techniques. Furthermore, all reagents were irradiated with ultraviolet light to inactivate any possibly contaminated double-stranded DNA that may have already existed in the reagents.[14] Fifty nanograms of human DNA or 10 ng of *Escherichia coli* DNA was used as a negative control that always yielded negative results in chlamydial DNA amplification reactions. Multiple reagent controls also were included in every polymerase chain reaction assay and always gave negative results. Repeated DNA amplification assays of the same specimens at different times or by different staff members produced the same results.

Results

The presence of chlamydial DNA is suggested by the appearance of the 182 base pair DNA after amplification (Fig. 1, lane B). The lower limit of detection of our method (i.e., DNA amplification by polymerase chain reaction followed by Southern blot hybridization with a ^{32}P-labeled internal oligonucleotide probe) is approximately a single chlamydial genome equivalent. The estimation of this sensitivity was reached by amplifying serial dilutions of chlamydia (ATCC-VR 885) of known infection titers in McCoy cells (data not shown). The level of detection is not adversely affected by the presence of as much as 50 ng of human or 10 ng of bacterial *E. coli* DNA in the specimens. DNA prepared from *Mycoplasma hominis, Mycoplasma pneumoniae,* human papillomaviruses (types 6, 11, 16, 18, and 33), human cytomegalovirus, and herpes simplex viruses (types I and II) do not cross amplify with the chlamydial primers used in this study (data not shown).

The authenticity of the amplified DNA and the specificity of the amplification reaction were evaluated and confirmed with two independent methods. First, the sizes of DNA after restriction endonuclease *Hha* I digestion of the amplified DNA, predicted from known DNA sequences and location of *Hha* I restriction site, were confirmed by the actual size produced after *Hha* I digestion. When the amplified chlamydial DNA was treated with restriction endonuclease *Hha* I, the original 182 base pair DNA disappeared and was replaced with new DNA of 150 and 32 base pairs (Fig. 1, lanes B and D). Second, Southern blot hybridization showed that the 182 base pair DNA, produced by amplifying DNA prepared from chlamydia-infected McCoy cells and from cervicovaginal cells and amniotic fluid of a patient with chlamydial infection, hybridized with the oligonucleotide probe specific for chlamydial DNA sequences (Fig. 2).

Chlamydial DNA sequences were found in cervicovaginal cell specimens of 9 of 31 (29.0%) pregnant women in this study (Table I). The cervicovaginal chlamydia positivity was confirmed by culture in only five of these nine chlamydial DNA–positive individuals. All five of the patients who had positive test results for chlamydia by both DNA and culture have clinical signs of mild mucopurulent cervicitis. Chlamydial DNA, on the other hand, was found in amniotic fluid specimens of two of nine (22.2%) women who had positive results for cervicovaginal chlamydial DNA. Of these two intraamniotic chlamydial DNA–positive individuals, one had positive results and one had negative results of both cervicovaginal cells and amniotic fluid cultures (Table

Fig. 2. Southern blot DNA hybridization of amplified *C. trachomatis* DNA with internal oligonucleotide probe. *Lane A* is amplification of DNA prepared from McCoy cells infected with ATCC reference strain of chlamydia, whereas *lane B* is from uninfected McCoy cells. *Lanes C and D* are amplifications of DNA prepared from cervicovaginal cells and amniotic fluid, respectively, of chlamydia-free patient. *Lanes E and F* are amplifications of DNA prepared from cervicovaginal cells and amniotic fluid, respectively, of patient with chlamydial infection. *Lane G* is primer-negative control. Exposure time for autoradiograph was 24 hours.

Table I. Prevalence of chlamydial DNA and culture in cervicovaginal cells and amniotic fluid

No. of patients	*Cervicovaginal cell*		*Amniotic fluid*	
	DNA	*Culture*	*DNA*	*Culture*
22	Negative	Negative	Negative	Negative
3	Positive	Negative	Negative	Negative
1	Positive	Negative	Positive	Negative
4	Positive	Positive	Negative	Negative
1	Positive	Positive	Positive	Positive

I). None of the amniotic fluid specimens from the remaining 22 cervicovaginal chlamydial DNA–negative women were found to contain chlamydial DNA. In a separate study the rate of positive chlamydial cultures was determined to be 11% among the general population (data not shown).

Comment

Genital chlamydial infections in women are important not only because they are frequent but also because the consequences can be serious. Among women with urogenital chlamydial infection, an estimated 10% can result in acute salpingitis. Subclinical endometrial infection can be rather frequent,[15] and a high proportion of women with involuntary infertility associated with bilateral tubal damage do not report a history suggestive of prior pelvic infection; therefore it is likely that the proportion of chlamydial infection with significant ascending but subclinical infection is much greater than the estimated 10%. A sensitive and reliable diagnostic method for *C. trachomatis* is important and needed for early diagnosis of subclinical chlamydial infections and for effective treatment.

Results reported here seem to have satisfied the two primary goals we set for this study: to examine the feasibility of using the polymerase chain reaction to detect chlamydia and to examine the prevalence of subclinical chlamydial infections. We have detected significantly more chlamydia by the polymerase chain reaction DNA amplification method than by the culture method (Table I), and the most likely reason for this difference is the higher sensitivity of the polymerase chain reaction method. False positivity probably did not contribute to the high DNA-positive rate because laboratory contaminations have been kept to the very minimum with various control measures, and the authenticity of the amplified chlamydial DNA was evaluated and confirmed by two independent methods. Although there is no direct evidence indicating that chlamydia can multiply in cells found in amniotic fluid, preliminary data from polymerase chain reaction amplification of ribonucleic acid suggested that chlamydia-specific messenger ribonucleic acid could be found in certain amniotic fluid specimens that are positive for chlamydial DNA (data not shown).

The pathways of intraamniotic chlamydial infection are not clear now, but the strong association between urogenital and intraamniotic chlamydial infections seems to suggest that ascension from the vagina and cervix may be the likely route through which chlamydia gains access to the amniotic cavity.

A number of microorganisms, including *C. trachomatis*[16] and others like *Gardnerella vaginalis, M. hominis,*[17-19] *Ureaplasma urealyticum,*[18, 19] human papillomavirus,[20] cytomegalovirus,[21] and human immunodeficiency virus,[22] have been identified or isolated from amniotic fluid or fetus. Some of them are known to be able to cause prenatal or congenital infections of the fetus.[21, 22] The presence of chlamydial DNA sequences by itself does not represent the presence of infectious chlamydia, but our results do suggest that the intraamniotic presence of chlamydia in women with urogenital chlamydial infection is probably not an infrequent event. The intraamniotic detection of chlamydia may suggest an in utero mechanism by which chlamydia can be transmitted before birth. However, the clinical significance and consequences of intraamniotic chlamydial infection need to be investigated further in light of the fact that none of the women with amniotic chlamydial infections in our study were reported to have chorioamnionitis, premature rupture of membranes, or preterm labor.

The results reported here underscore the frequency and importance of intraamniotic chlamydial infections in women with urogenital chlamydial infections. There is a definite need now for more detailed prospective studies on the relationship between intraamniotic chlamydial infections and infant morbidity.

We acknowledge the encouragement and support of Dr. Chau-Hsiung Chang and Dr. Delon Wu. We also acknowledge the excellent technical assistance of Ms. ShihHwa Shen with some of the experiments.

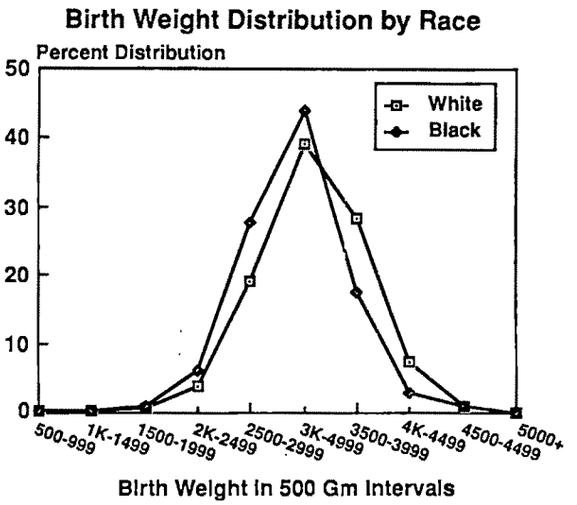
Birth weights of infants of black and white mothers without pregnancy complications

Thomas C. Hulsey, MSPH, ScD,[a] Abner H. Levkoff, MD,[a] and Greg R. Alexander, MPH, ScD[b]

Charleston, South Carolina, and Minneapolis, Minnesota



An analysis of 10,159 normal spontaneous vaginal deliveries was performed to examine racial differences in mean birth weight of infants whose mothers were without antepartum or intrapartum medical complications of pregnancy. The study was limited to black and white infants of low-income mothers who were inborn, singleton, and weighed ≥500 gm at birth. High-risk maternal transfer patients and patients with hypertension, toxemia, bacteriuria, pyelonephritis, renal failure, diabetes, anemia, polyhydramnios, oligohydramnios, prolapsed cord, vaginal bleeding, placenta previa, abruptio placentae, prolonged rupture of membranes, maternal fever on admission, amnionitis, sexually transmitted diseases, or fewer than five prenatal care visits were excluded. When statistically significant differences in demographic characteristics were controlled, black infants had an average birth weight 181 gm less than that of white infants. (AM J OBSTET GYNECOL 1991;164:1299-302.)

Key words: Birth weight, newborn, race, gestational age

Studies examining racial differences in mean birth weight have identified significant independent associations between birth weight, race, maternal demographic characteristics,[1, 2] and medical risk factors.[3] When differences in measured demographic characteristics or medical complications were controlled, significant racial differences in the mean birth weight remained.[4, 5] However, controlling for differences in the incidence of medical complications remains problematic, because the potential effects of racial differences in disease severity and compliance with therapy have not been considered.

To our knowledge no previous study of low-income mothers has attempted to control for the influence of medical complications of pregnancy on racial differences in mean birth weight by examining patients without such complications. A study so designed would also reduce the potential influence of unmeasured factors

that are related to specific medical complications of pregnancy. More directly, do the observed racial differences in mean birth weight remain after the potential influences of disease are removed?

Material and methods

The Medical University Hospital is a regional perinatal center providing care for a predominantly low-income population, with 71.6% of deliveries during the past 7 years classified as indigent or Medicaid. Hospital records of all deliveries are routinely abstracted, and information from both maternal and newborn charts is entered into a computerized perinatal data base.[6] The validity and reliability of this data base are increased through extensive training of data clerks and regular checks for abstraction and coding errors.

Black and white mothers who were delivered between Jan. 1, 1981, and Dec. 31, 1987, were selected for the present study. Only singleton, live-born infants ≥500 gm delivered of black or white mothers who had at least five prenatal care visits were selected. To minimize the selection bias that may have resulted from high-risk maternal transfers, mothers who had been referred from another hospital were omitted from the study. In addition, many of the private patients who elected Medical University Hospital for delivery may have done so because of some previous poor pregnancy outcome. To minimize the latter bias, only nonprivate patient records were examined. Mothers who were delivered by cesarean section or vaginally after induction of labor also were excluded from study. In both instances the infant's birth weight could have been affected by an elective, iatrogenic termination of pregnancy, and it was unknown whether a trial of labor was attempted.

Table I. Comparison of maternal and infant characteristics by race

	Black	*White*	*p Value*
Single	69.2	32.9	0.0001
Mean height (inches)	64.1	64.1	0.95
Mean weight at delivery (lb)	163.7	160.1	0.0001
Education <12 yr (%)	45.3	60.7	0.0001
Primigravid (%)	33.8	34.9	0.26
Mean maternal age (yr)	22.7	22.2	0.0001
Low birth weight (%)	7.8	4.9	0.0001
Very low birth weight (%)	0.7	0.5	0.13
Mean gestational age (wk)	39.5	39.5	0.30
Mean head circumference (cm)	33.9	34.4	0.0001
Mean length (cm)	50.2	50.8	0.0001
Preterm (%)	4.0	3.9	0.85
Mean birth weight (gm)	3138	3322	0.0001

The maternal medical complications selected for exclusion were hypertension, toxemia, bacteriuria, pyelonephritis, renal failure, diabetes, anemia, polyhydramnios, oligohydramnios, prolapsed cord, vaginal bleeding, placenta previa, abruptio placentae, prolonged rupture of membranes, maternal fever on admission, amnionitis, and sexually transmitted diseases. Therefore the study population was limited to normal spontaneous vaginal deliveries free of major medical complications of pregnancy and homogeneous as to income, medical care, and predisposing perinatal risk. Of the total 22,949 births that occurred during the time period under investigation, 10,159 (44.3%) met all criteria for entry (6820 black and 3339 white).

Maternal demographic characteristics included mother's marital status, height, weight at delivery, age, gravidity, education, and race. Infant factors included birth weight, length, birth head circumference, and gestational age.[7]

Statistical analysis (Student's t test for continuous variables and χ^2 for categoric variables) first determined whether maternal demographic characteristics between

Table II. Regression analysis of demographic characteristics

Variable	*β**	*p Value*
Single marital status	−56.0	0.0001
Weight at delivery	4.7	0.0001
Education <12 yr	−9.06	0.36
Mother's age	2.4	0.02
Black race	−181.4	0.0001

Model: $R^2 = 0.14$; $p < 0.0001$; $N = 10{,}159$; F = 295.1; intercept = 2602.8.

*β-Coefficients reflect average change in birth weight (in grams) given a unit change of associated variable and with control for all other listed variables.

blacks and whites were significantly different. The effects of those factors that differed significantly between blacks and whites were simultaneously controlled by a linear regression model, and the adjusted mean birth weights were examined. The final model presents the average difference in mean birth weight in nonprivate, nonreferred, normal spontaneous vaginal deliveries between black and white women after statistically significant population differences were controlled.

Results

Maternal demographic and infant outcome characteristics are presented in Table I. The characteristics for which race was not statistically different were average maternal height at delivery and the proportion of primigravid women. Compared with black mothers, white mothers were more often married, weighed less at delivery, had completed fewer years of education, and were younger. The mean birth weight for black infants was 184 gm less than that for white infants. The reduced mean birth weight for black infants was accompanied by a significantly shorter mean length and smaller mean head circumference. The incidence of low birth weight was significantly higher in blacks. There were no significant racial differences in mean gestational age, incidence of preterm deliveries, or incidence of very-low-birth-weight births (birth weight <1500gm). Whereas the gestional age distribution was similar in both groups of infants, the birth weight distribution for white infants was shifted to the right (Fig. 1). The birth weight distribution shift between race groups was evident in both term and preterm infants (Fig. 2). The regression results in Table II suggest that maternal age and weight at delivery demonstrated a positive association with infant birth weight. Single marital status and maternal education <12 years was negatively associated with infant birth weight. After we simultaneously controlled for these factors, black infants continued to show an average birth weight 181.4 gm less than that of white infants.

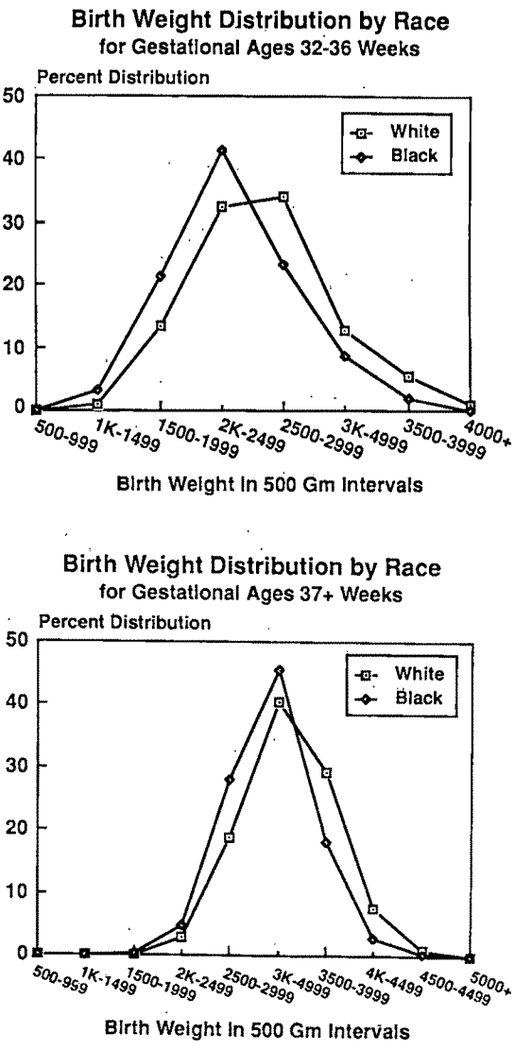

Fig. 2. Birth weight percent distribution by race and gestational age groups (32 to 36 and ≥37 weeks).

Comment

Previous epidemiologic reports have defined the discordance of mean birth weight between black and white infants to be approximately 200 gm, with black infants consistently weighing less than white infants. The cause of this mean weight difference, whether medical, environmental, or genetic, remains unanswered. The present study addresses the medical component by evaluating the birth weights of infants born by spontaneous vaginal delivery to low-income black and white mothers who had no medical complications of pregnancy.

This investigation suggests that, after attempts to eliminate the potential effects of medical complications and control for differences in maternal demographic characteristics, black infants continued to show a mean

birth weight that was significantly lower than that of white infants. While having a similar gestational age distribution, black infants were characterized by a statistically significant shorter average length and smaller average head circumference. Given the similarity of gestational maturity, a concomitant reduction in mean birth weight, mean length, and mean head circumference are consistent with symmetric growth reduction. The biologic basis of these differences remains unclear. Birth weight differences apparently were not due to a higher incidence of preterm gestational age among blacks or to the increased incidence of low birth weight in blacks. The low-birth-weight infants accounted for only a small portion of the 184 gm mean difference observed.

Several limitations should be addressed in comparing these two groups of mothers. Weight at delivery may not equate with nutritional status, nor years of schooling with quality of education, nor level of low income with depth of poverty. Gestational age at which prenatal care was initiated was not available and therefore was not assessed. Potential underreporting of medical complications and small cell sizes in the lower weight categories also may limit interpretation.

This investigation used the neonatal assessment to estimate gestational age. In this way neurologic and physical maturity were considered (rather than simply length of gestation). This allowed us to investigate whether reductions in birth weight were accompanied by differences in gestational maturity. The result would provide additional information as to the clinical implications of birth weight differences.

Given these limitations, however, this study suggests that in a moderately large population of low-income black and white parturients, without the known influence of medical complications of pregnancy and with controls for demographic differences, the mean size of black infants remained significantly smaller than that of white infants. Further, this difference was not accompanied by an equivalent difference in gestational maturity.

Incidence of genital herpes simplex virus at the time of delivery in women with known risk factors

Patrick M. Catalano, MD, Alice O. Merritt, RN, and Philip B. Mead, MD
Burlington, Vermont

A total of 143 women with known risk factors for genital herpes simplex virus had cultures performed at the time of delivery. A total of 123 were without symptoms, of which three (2.4%) had positive herpes simplex virus cultures at the time of delivery. Fifteen women had lesions clinically consistent with genital herpes simplex virus at the time of delivery and five (33.3%) were culture positive. Five women had only prodromal symptoms of genital herpes simplex virus, but two of these (40%) had positive herpes simplex virus cultures from the site of previous lesions. Of the 10 women with positive herpes simplex virus cultures in this group of 143, no infant was delivered with evidence of neonatal herpes simplex virus infection, including two who had vaginal deliveries. The results of this study support the recommendations that in women without symptoms but with known risk factors for genital herpes simplex virus, a trial of vaginal delivery be allowed and that in women with either a lesion clinically consistent with genital herpes simplex virus or prodromal symptoms of genital herpes simplex virus a cesarean section be the mode of delivery. (AM J OBSTET GYNECOL 1991;164:1303-6.)

Key words: Maternal herpes simplex virus, parturition

The incidence of genital herpes simplex virus (HSV) infections has increased dramatically in the past decade.[1] Despite this fact, the management of genital HSV in obstetric patients at the time of delivery remains controversial. Protocols for obstetric management have as their goal the protection of the fetus from contact with HSV during labor and delivery. Although this mandates cesarean section in patients in labor with clinically active HSV lesions, the appropriate management of patients who might be shedding virus asymptomatically is less clear. Few studies have even assessed the incidence of asymptomatic HSV shedding during the intrapartum period. Harger[2] and Wittek[3] found a 1.9% to 2.3% rate of positive genital HSV cultures in pregnant women without symptoms who were at risk of genital HSV late in gestation. However, the only study that prospectively examined the incidence of positive genital HSV cultures at the time of delivery in women without symptoms but with a past history of genital HSV was that of Arvin et al.[4] who found an incidence of 0.96%.

Furthermore, asymptomatic shedding is unlikely to result in fetal infection. The observed risk of neonatal infection in 34 infants delivered vaginally to such women was zero in one study.[5] On the basis of this sample size, the 95% confidence interval for the neonatal infection rate is 0% to 8%. Because the neonatal infection rate will be the product of this low attack rate multiplied by the rate of asymptomatic genital shedding, confirmation of Arvin's[4] low incidence of shedding at delivery would suggest an extremely small neonatal infection risk in this setting. In accordance, this study was designed to determine the incidence of genital HSV shedding at the time of delivery in women with risk factors for such shedding.

Material and methods

Subjects. This study was performed at the Medical Center Hospital of Vermont from 1984 through 1988. This hospital serves a population that is predominantly from the middle socioeconomic class. The study was approved by the Institutional Review Board at the University of Vermont, and informed consent was obtained from each participant. Women with either a past history of genital HSV, a sexual partner with genital HSV, or first episode of genital HSV infection during the index pregnancy were recruited antepartum to participate in this study.

Study design. Each woman received routine antepartum care from her primary obstetrician. The guidelines for the management of women at risk of genital HSV at the Medical Center Hospital of Vermont during the time of study consisted of weekly genital cultures for HSV during the last 4 weeks of pregnancy. Women whose most recent genital HSV cultures were negative and who were without symptoms on admission to the Labor and Delivery Unit were allowed to attempt vaginal delivery. Each patient had a genital and speculum examination for HSV at the onset of labor by the at-

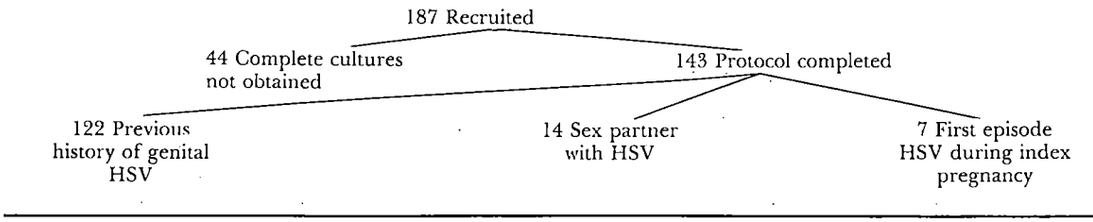

Fig. 1. Risk factors for genital HSV.

tending obstetrician or house officer. Women with a positive genital HSV culture within 1 week of delivery, a lesion clinically consistent with genital HSV lesion, or prodromal symptoms of genital HSV on admission to the Labor and Delivery Unit, were usually delivered by cesarean section. Individual intrapartum management decisions were made by the attending obstetrician.

For the purposes of this study, on admission to the Labor and Delivery Unit, a HSV culture was obtained from the woman's cervix and the usual site of lesion. A delivery record that described any lesions or symptoms of genital HSV and route of delivery was completed. The maternal obstetric record was reviewed and the number of episodes of genital HSV that were documented by the physical examination and positive HSV cultures obtained during the index pregnancy were noted. Last, each neonatal record was reviewed to determine whether HSV lesions were noted, cultures were obtained, and antiviral treatment was instituted.

HSV culture method. Cultures were obtained with a cotton-tipped swab. The swab was placed in a phosphate-buffered base transport medium. The medium contained distilled water, amphotericin B, gentamicin, fetal bovine serum, and sucrose. A total of 45% (64/143) of the cultures were performed at the Medical Center Hospital of Vermont. Aliquots of the transport medium were then inoculated into each of two tube cultures, one of which contained human fibroblasts and the other rabbit kidney cells. They were observed daily for evidence of characteristic cytopathic effects. A total of 55% (79/143) of the cultures were immediately placed in a −80° C freezer and later cultured at the University of Rochester virology laboratory because Dr. Richard Reichman, whose laboratory performed the HSV cultures, moved to Rochester during the time this study was in progress. The aliquots (0.2 ml) of the transport medium were then inoculated into each of two tube cultures of human diploid fibroblast cells and observed daily for evidence of characteristic cytopathic effects.

Results

Of the 187 women who were recruited for this study and who had a past history of genital HSV, a sexual partner with HSV, or clinical primary genital HSV infection during the index pregnancy, 143 completed the study. As shown in Fig. 1, 85% (122/143) had a previous history of genital HSV, 10% (14/143) had a sexual partner with only genital HSV, and 5% (7/143) had a first episode of genital HSV during the index pregnancy. The other 44 women had HSV cultures that were either lost because of a laboratory error or not obtained at the time of delivery.

Of the 136 patients who were at risk because of either a prior history of genital HSV or a partner with genital HSV, 27% (37/136) were documented to have a recurrent HSV lesion by physical examination during the index pregnancy—6 during the first trimester, 14 during the second trimester, and 17 during the third trimester. In these same patients, 29% (40/136) had a positive genital HSV culture during pregnancy—three during the first trimester, nine during the second trimester, and 28 during the third trimester. Hence, 45% (61/136) of patients with either recurrent genital HSV or a partner with genital HSV had either a genital HSV lesion or positive genital HSV culture during the index pregnancy.

Of the seven patients with a first episode of genital HSV infection during the index pregnancy, 57% (4/7) had a positive genital HSV culture—two in the second and two in the third trimester.

Incidence of genital HSV at the time of delivery. The results of the genital HSV cultures at the time of delivery are given in Table I. A total of 86% (123/143) of the patients were without symptoms at the time of delivery. Of the patients without symptoms, 2.4% (3/123) had a positive genital HSV culture.

A total of 10% (15/143) of the patients had a lesion clinically consistent with a genital HSV at the time of delivery, and 33% (5/15) had a positive genital HSV culture. Last, 4% (5/143) of the patients had only prodromal symptoms of genital HSV, and 40% (2/5) had a positive genital HSV culture.

Mode of delivery. Of the 123 women without symptoms 70% (86/123) had a vaginal delivery and 30% (37/123) were delivered of infants by cesarean section because of various indications. It is of note that 5% (6/123) of these women had a cesarean section solely on the basis of a history of genital HSV. In addition, two women were delivered of infants by cesarean section because of a positive genital HSV culture 1 to 3 days before delivery, although both had negative genital HSV cultures the day of delivery.

Two of the three women without symptoms but with a positive genital HSV culture the day of delivery were delivered of infants by cesarean section. One of these women had a labial lesion and positive HSV culture 1 week before delivery and the other women had a positive genital HSV culture 6 days before delivery. The third woman had a vaginal delivery, and it is of note that she had a negative genital HSV culture the day before delivery.

Of the 15 women with a question of a genital HSV lesion, 80% (12/15) were delivered of infants by cesarean section. One woman with a labial lesion had a precipitate vaginal delivery and a positive cervical HSV culture. The other two women were allowed vaginal deliveries and had negative genital HSV cultures.

In the five women with prodromal symptoms of HSV, four were delivered of infants by cesarean section because of their symptoms. One woman with a negative genital HSV culture had a vaginal delivery.

Neonatal outcome. All infants delivered of the 143 study subjects were healthy at the time of delivery and none had clinical evidence of neonatal HSV infection. Four infants were cultured for HSV and all cultures were negative.

Comment

The results of this study are comparable with the results of the study by Arvin et al.,[4] which was the only other study to prospectively examine the incidence of positive genital HSV cultures in an at-risk population at the time of delivery. The incidence of positive maternal genital HSV cultures in women without symptoms at delivery was 0.96% (3/311) in Arvin's study[4] in comparison with 2.4% (3/123) in our study.

However, Arvin's study[4] differed from ours in that the neonatal oropharynx, in addition to maternal genital HSV cultures, were obtained at the time of birth in their study. Two neonates, whose mothers had negative genital HSV cultures, had positive HSV cultures. Therefore the total incidence of asymptomatic shedding of genital HSV at the time of delivery was 1.4% (5/354). Neonatal cultures for HSV were not obtained routinely from our study population. In addition, Arvin's[4] patient population differed from ours in that they evaluated only women with a history of recurrent genital HSV infection, whereas 15% of our study population included women with either a partner with genital HSV (10%) or first episode of genital HSV (5%).

Although our study did not specifically address the question of whether antepartum maternal genital HSV cultures predicted which women without symptoms would have a positive genital HSV culture at the time of delivery, our results support the findings of Arvin[4] and Wittek[3] that antenatal genital HSV cultures are of little predictive value. The short mean duration of viral shedding with recurrent HSV late in pregnancy (3.6 ± 2.8 SD days as reported by Harger et al.[2]) and the fact that cultures for HSV have a sensitivity of <100%[6] may help to explain the poor predictive value of weekly genital HSV cultures in this population.

Table I. Incidence of genital HSV at delivery

Clinical status	*No. positive*	*No. cultured*	*%*
No. symptoms	3	123	2.4
HSV lesion	5	15	33.0
Prodromal symptoms	2	5	40.0

The incidence of positive HSV cultures in women with a lesion clinically consistent with genital HSV at delivery was between 20% to 30% in our study and that of Arvin.[4] These results support the generally accepted recommendation for cesarean section as the mode of delivery in these women. Moreover, we would also recommend cesarean section as the mode of delivery in those women with a history of recurrent genital HSV and prodromal symptoms of HSV. A total of 40% (2/5) of the women in this study and 20% (1/5) of the women in Arvin's study[4] had positive HSV cultures. Prodromal symptoms may be one of earliest manifestations of recurrent HSV in an at-risk population.

Optimal management of women without symptoms but with a history of genital HSV at the time of delivery is yet to be determined. However, our results support the current recommendations at the American College of Obstetricians and Gynecologists,[7] that a trial of vaginal delivery be allowed in such women. Furthermore, we recommend cesarean section as the mode of delivery in women with known risk factors for genital HSV and either a lesion consistent with genital HSV lesion or prodromal symptoms. The limitation of current management protocols to decrease the incidence of neonatal HSV infection, however, needs to be recognized. A recent national surveillance study for neonatal HSV infection by Stone et al.[8] showed that in a series of 184 cases of neonatal HSV infection, 78% of the mothers had no history of genital HSV infection. Furthermore, cesarean section before rupture of membranes failed to prevent neonatal HSV infection in 15 cases. Therefore future studies that examine the role of factors such as the titers of maternal neutralizing antibody, the development of accurate and rapid diagnostic tests at the time of delivery, and the potential use of antiviral agents during pregnancy are needed to decrease the incidence of neonatal HSV infection.

We thank Dr. Richard Reichman for his assistance in performing the HSV cultures in his laboratory.

The clinical utility of maternal body mass index in pregnancy

Honor M. Wolfe, MD,[a] Ivan E. Zador, PhD,[a] Thomas L. Gross, MD,[b] Susan S. Martier, MSSA,[a] and Robert J. Sokol, MD[a]

Detroit, Michigan, and Peoria, Illinois

To describe maternal body mass index and to compare the use of maternal weight and body mass index for risk assessment at the initial prenatal visit, 6270 gravid women who were consecutively delivered of infants were studied. Body mass index increased with advancing maternal age, parity, and advancing gestational age and was significantly greater in black women than in nonblack women. Risks for the development of adverse outcome associated with maternal obesity, including development of gestational diabetes, preeclampsia, fetal macrosomia, and shoulder dystocia, were comparably predicted by either maternal weight or body mass index >90th percentile. Maternal weight was as predictive of preeclampsia, macrosomia, and shoulder dystocia as was body mass index when these factors were analyzed as continuous variables, whereas increasing body mass index was more predictive of gestational diabetes. The prediction of factors associated with low maternal weights, small-for-gestational-age birth, prematurity, low birth weight, and perinatal death was equivalent for maternal weight and body mass index that was <10th percentile. This study indicates that in the initial risk assessment of outcomes related to maternal weight, the calculation of maternal body mass index offers no advantage over simply weighing the patient. This finding contrasts with results in nonpregnant women. (Am J Obstet Gynecol 1991;164:1306-10.)

Key words: Maternal weight, body mass index, perinatal risk, gestational diabetes

Many studies examining the effect of maternal size on pregnancy outcome relied on maternal weight (<100 and >200 pounds) to define risk categories at the initial prenatal visit.[1-3] More recently, risk assessment related to body size has been based on some measure of maternal weight for height.[4-6] Studies in the medical literature suggest that maternal body mass index, calculated as body weight (kilograms)/(height [meters])^2, is superior to weight alone for the prediction of morbidity and mortality in nonpregnant populations.[7,8] Because of the direct and continuous relationship of body mass index with outcome, its strong correlation with levels of adiposity, and its independence of height, a recent National Institutes of Health study[9] has recommended the use of body mass index as a measure of relative leanness in nonpregnant populations. In spite of the widespread use of maternal body mass index in the obstetric literature, we know of no studies to date that compare the relative validity of using maternal weight for height and maternal weight in the initial risk assessment for weight-associated outcomes in pregnancy.

Our purpose in this study was to describe body mass index and its determinants in pregnancy and to see

whether consideration of maternal weight for height (as calculated in the body mass index) leads to the better prediction of perinatal and maternal morbidity than does weight alone.

Material and methods

We selected women for study who were consecutively delivered of infants at Hutzel Hospital over a 30-month period and for whom antepartum and intrapartum records were available. Maternal and neonatal data were obtained from a computerized perinatal data base previously described.[10] Table I lists the variables obtained for each patient.

Body mass index was calculated from weight and height measured at the initial prenatal visit as weight (kilograms)/(height [meters])^2.

The effect of maternal characteristics on body mass index was examined by multiple regression with body mass index from the first prenatal visit as the dependent variable. Independent variables included maternal age, gestational age at the initial visit, race (coded as black vs nonblack), and maternal parity.

Maternal body mass index and maternal weight were then examined as continuous variables for their association with adverse outcomes associated with maternal size. To examine the relative predictive validity of maternal body mass index and weight in pregnancy, each factor was allowed to compete as an independent variable in separate discriminant function analyses against outcome variables previously associated with high and low maternal weight. Outcome (dependent) variables related to maternal obesity included gestational diabetes, preeclampsia, and the birth of a macrosomic infant (>4000 gm). Those variables associated with low maternal weight included the birth of a small-for-gestational-age infant, birth weight <10th percentile, very-low birth weight (<1500 gm), preterm birth (<37 weeks' gestation), and perinatal mortality. Maternal age, parity, race, marital status, gestational age at initial prenatal visit, and substance use were included as potentially confounding independent variables.

The relative risk for these adverse outcomes was then calculated for small maternal size (body mass index or maternal weight <10th percentile) and large maternal size (body mass index or maternal weight >90th percentile). Relative risks and the 95% confidence intervals[11] were calculated according to the method of Woolf.

Results

Table I summarizes the characteristics of the 6270 women studied. The group studied was predominantly black (79%) with a mean maternal age of 25 ± 6 years. The mean maternal body mass index at the first prenatal visit was 26.5 ± 6.5 kg/m^2 (64 inches, 155 pounds). The 10th percentiles for maternal weight and body mass index were 115 pounds and 20.1 kg/m^2, respectively; the 90th percentiles were 208 pounds and 35.2 kg/m^2.

Table I. Characteristics of 6270 women studied

Factor	*Mean ± SD*	*Range*
Age (yr)	25.1 ± 6.0	12-52
Gravidity (yr)	3.0 ± 1.9	1-16
Parity	1.1 ± 1.4	0-11

Tobacco	23.7	
Marijuana	7.4	
Narcotic	6.5	
Alcohol abuse	4.1	

*Patient recall.

Results of the multiple regression for determinants of maternal body mass index are summarized in Table II. When considered individually (step 0), body mass index was found to increase with increasing maternal age, parity, and advancing gestational age. Black women had a significantly greater body mass index than did nonblacks (26.8 vs 25.5 kg/m^2, respectively). This was true in spite of the fact that, on average, black mothers were significantly younger than nonblack mothers (24.2 vs 27.6 years). Body mass index decreased with a maternal history of alcohol, narcotics, or tobacco use. When considered jointly (at the final step), all maternal factors remained significant, with a total of 9.7% of the variance in body mass index explained by these variables.

When maternal body mass index and weight were examined as continuous variables, as shown in Table III, discriminant analysis revealed that of the outcome variables associated with maternal obesity, only gestational diabetes mellitus was better predicted by increasing maternal body mass index than by weight. Even

*At first prenatal visit.

when maternal weight was forced into the model at level 1, body mass index significantly improved the prediction of gestational diabetes. Indeed, increasing maternal body mass index was more predictive of the development of gestational diabetes than of advancing maternal age. Macrosomia, shoulder dystocia, and preeclampsia were comparably predicted by increasing maternal weight and body mass index, which were considered as continuous variables.

The study also examined outcomes associated with low maternal weight. Discriminant function analysis demonstrated that the birth of small-for-gestational-age infants was most closely associated with narcotic use; decreasing maternal weight explained minimal additional variance.

In this study, perinatal mortality, very low birth weight, and preterm births were not predicted by either maternal body mass index or weight, when these were considered as continuous variables.

Relative risks for outcomes associated with maternal obesity were comparable for maternal weight or body mass index >90th percentile (Table IV). Similarly, relative risks for adverse outcomes associated with low maternal weight were equal for maternal weight or body mass index <10th percentile (Table V).

Comment

This is the first study, of which we are aware, that describes determinants of maternal body mass index and compares maternal body mass index with maternal body weight for the strength of their associations with perinatal outcomes. Maternal factors, including age, race, parity, substance use, and gestational age, all were significantly related to body mass index and explained approximately 10% of its variance. Although diabetes mellitus was more strongly associated with maternal body mass index than with maternal weight, four of the five outcomes significantly related to maternal size (macrosomia, preeclampsia, and infants who were either small or large for gestational age) were more strongly related to weight than to body mass index. In contrast to previous data in nonpregnant populations, this study suggests that, in the pregnant patient, body weight is comparable to body mass index for the prediction of key adverse, weight-associated outcomes.

This study was not designed to examine the well-established association between maternal size or weight gain and perinatal or maternal outcome. Rather, data were analyzed to address the more basic question of whether this relationship might be better expressed by the recent trend in the medical and obstetric literature

Table IV. Comparison of relative risk for occurrence of outcomes associated with maternal obesity for body mass index or weight >90th percentile

Outcome	*Maternal size assessment*	*Relative risk*	*95% Confidence interval*
Gestational diabetes	Body mass index >90th percentile	5.31	3.83-7.34
	Weight >90th percentile	4.18	3.03-5.75
Preeclampsia	Body mass index >90th percentile	2.26	1.71-2.99
	Weight >90th percentile	2.49	1.93-3.21
Macrosomic infant	Body mass index >90th percentile	2.54	1.94-3.33
	Weight >90th percentile	2.77	2.16-3.55
Large-for-gestational-age infant	Body mass index >90th percentile	2.05	1.62-2.59
	Weight >90th percentile	2.49	2.00-3.09
Shoulder dystocia	Body mass index >90th percentile	1.80	0.89-3.66
	Weight >90th percentile	3.50	0.14-3.19

Table V. Comparison of relative risk for outcomes associated with low maternal weight for body mass index or weight <10th percentile

Outcome	*Maternal size assessment*	*Relative risk*	*95% Confidence interval*
Small-for-gestational-age infant	Body mass index <10th percentile	2.07	1.58-2.72
	Weight <10th percentile	2.07	1.59-2.70
Premature infant	Body mass index <10th percentile	1.64	1.24-2.17
	Weight <10th percentile	1.83	1.41-2.38
Low-birth-weight infant	Body mass index <10th percentile	2.09	1.64-2.66
	Weight <10th percentile	2.31	1.84-2.89
NICU admission*	Body mass index <10th percentile	1.25	0.88-1.78
	Weight <10th percentile	1.42	1.01-1.98

*Neonatal intensive care unit admission.

toward the use of body mass index. We found that body mass index was superior to maternal weight only for identifying risk for gestational diabetes. It is not surprising that diabetes correlates better with body mass index, because insulin resistance is more a function of fat content than of absolute weight. This may reflect the fact that body mass index is more sensitive than weight to obesity in shorter women. Thus, for example, a woman who is 5 feet tall and weighs 180 pounds has a body mass index in the "obese" range (35.3 kg/m^2), although she does not meet the weight criteria for obesity.

Body mass index is used to define relative leanness and weight-associated outcomes in nonpregnant populations. It is not clear why this did not appear to apply to pregnant women. This study was performed with a sample of indigent, black, inner-city gravid women. The mean prepregnancy body mass index in this study (24.3 kg/m^2) was higher than the "ideal" body mass index for nonpregnant populations (22.5 kg/m^2).[9] Therefore our results may not be entirely applicable to other populations. In addition, although body mass index correlates with the percent of fat, body mass index does not distinguish between various body components such as muscle and fat. Because our patients sought prenatal care at a relatively late gestational age (20 weeks), this study cannot address the relative utility of maternal body mass index and weight in the first trimester.

Although in individual cases maternal body mass index may be helpful in defining risk as it is related to maternal size (particularly among women at either extreme of height), body mass index and weight appear to be of comparable use in large studies. Whereas much remains to be defined with respect to maternal leanness and perinatal outcome, this study suggests that the simple act of weighing the patient constitutes an important part of prenatal care and is adequate for the identification of most perinatal risk factors related to maternal size.

Complexes of activated protein C with α_1-antitrypsin in normal pregnancy and in severe preeclampsia

Francisco España, PhD,[a] Juan Gilabert, MD, PhD,[b] Justo Aznar, MD, PhD,[c] Amparo Estellés, MD, PhD,[a] Takao Kobayashi, MD,[c] and John H. Griffin, PhD[d]
Valencia, Spain, and La Jolla, California

Protein C is a vitamin K–dependent regulator of blood coagulation. Activated protein C is regulated in plasma in large part by two inhibitors, protein C inhibitor and α_1-antitrypsin. Complexes of activated protein C with both inhibitors in plasma samples from subjects with normal or pathologic pregnancy were measured. In normal pregnancy we observed a progressive and significant increase in activated protein C/α_1-antitrypsin complex levels, from 9 ± 3 ng/ml in the first trimester to 16 ± 3 ng/ml in the third trimester, as well as an increase in α_1-antitrypsin plasma levels. In severe preeclampsia, but not in chronic hypertension with superimposed severe preeclampsia, there was a greater increase in activated protein C/α_1-antitrypsin levels (25 ± 10 ng/ml) ($p < 0.001$) and a decrease in protein C and protein C inhibitor levels as compared with normal pregnant women at similar gestational ages. These data show an increase in the activation of the protein C pathway in both normal and pathologic pregnancy and provide evidence for an enhancement of thrombin generation in severe preeclampsia compared with chronic hypertension with superimposed severe preeclampsia. (AM J OBSTET GYNECOL 1991;164:1310-6.)

Key words: Protein C complexes, α_1-antitrypsin, pregnancy, preeclampsia, chronic hypertension

Alterations in hemostasis during normal gestation are widely known, and some obstetric complications, for example, preeclampsia, may increase the hypercoagulability state observed in pregnancy. Thus increased levels of coagulation factors[1, 2] and reduced fibrinolysis[3] have been demonstrated in preeclampsia. Disseminated intravascular coagulation has also been demonstrated in some cases of severe preeclampsia and eclampsia,[4] the action of the enzyme thrombin on fibrinogen being crucial in this process.

Activated protein C, the product of thrombin's action on protein C in the presence of endothelial cell thrombomodulin, together with its cofactor, protein S, regulates blood clotting by inhibiting the clotting cascade at the levels of factors Va and VIIIa.[5, 6] Activated protein C is regulated in plasma by two inhibitors, protein C inhibitor[7] and α_1-antitrypsin,[8] and complexes of activated protein C with both inhibitors have been reported to be circulating in vivo.[8, 9] The importance of the protein C anticoagulant system is illustrated by the fact that newborns with homozygous protein C deficiency suffer severe and generalized thrombotic disease,[10] and

Table I. Clinical and analytic data in normal and pathologic pregnancies

	Normal pregnancy, third trimester (n = 27)	*Preeclampsia* (n = 14)	*Chronic hypertension with superimposed severe preeclampsia* (n = 7)
Age (yr)	29 ± 4 (18-41)	28 ± 5 (21-37)	35 ± 4 (28-41)
Nulliparous women	15	12	1
Gestational age at sampling (wk)	36 ± 3 (29-41)	35 ± 6 (28-40)	33 ± 3 (28-37)
Birth weight (gm)	3245 ± 477	2277 ± 1210	2133 ± 1097
Placental weight (gm)	646 ± 126	514 ± 156	547 ± 157
Perinatal deaths	0	2	2
Hematocrit (%)	39 ± 3 (32-42)	34 ± 6 (26-41)	35 ± 3 (30-36)
Total bilirubin (mg/dl)	0.2 ± 0.1 (0.1-0.4)	0.4 ± 0.1 (0.1-0.6)	0.3 ± 0.1 (0.1-0.5)
Lactic dehydrogenase (IU/L)	137 ± 10 (100-178)	176 ± 52 (106-209)	177 ± 29 (138-215)
Aspartate aminotransferase (IU/L)	14 ± 8 (11-23)	15 ± 6 (9-23)	17 ± 6 (8-23)
Alanine aminotransferase (IU/L)	18 ± 8 (10-29)	21 ± 16 (8-56)	32 ± 21 (5-67)
Creatinine clearance (ml/min)	126 ± 10 (95-150)	90 ± 25 (60-119)	94 ± 37 (61-167)
Uric acid (mg/dl)	5 ± 1 (3-6)	6 ± 2 (2-7)	6 ± 1 (5-7)

Values are mean ± SD and range (shown in parentheses).

heterozygous protein C or protein S deficiency in some patients and their families is associated with venous thromboembolism.[11, 12] Recent evidence suggests that alterations in protein C pathway may be involved in thrombotic complications associated with normal and pathologic pregnancy. Functional and immunologic levels of protein S are decreased in normal pregnancy,[13, 14] and reduced levels of both protein C and protein S have been described in patients with severe preeclampsia.[14]

The purpose of this investigation was to gain qualitative and quantitative information regarding the activation and inactivation of protein C and its distribution between its two known inhibitors during normal and pathologic pregnancy, as a measure of the thrombin activity. In this study we measured protein C, protein C inhibitor, α_1-antitrypsin, and complexes of activated protein C with its two inhibitors during pregnancy and in patients with preeclampsia, and we report that activated protein C/inhibitor complexes are significantly increased during pregnancy and that patients with severe preeclampsia have activated protein C/α_1-antitrypsin complex levels twice as high as those in both chronic hypertension with superimposed severe preeclampsia and gestational age–matched controls.

Material and methods

Clinical groups

Control group. The control group for the pregnant groups comprised 20 normal nonpregnant women, aged 18 to 40 years (29 ± 5), who were not taking oral contraceptives and had no history of thromboembolic disease.

Normal pregnant group. Seventy-eight normal pregnant women, ranging from 18 to 41 years of age (29 ± 4), were included in the study. These women were grouped according to gestational age in first (n = 18), second (n = 33), and third (n = 27) trimester. No complications were noted during the pregnancies. They were nonsmokers and did not receive any type of medication except vitamin complexes.

Severe preeclampsia group. This group comprised 14 patients, aged 21 to 37 years (28 ± 5), with no previous history of hypertension but in whom a preeclamptic state developed during the third trimester of pregnancy. Criteria for severe preeclampsia, according to the Committee on Terminology of the American College of Obstetricians and Gynecologists,[15] were blood pressure ≥160/110 mm Hg and proteinuria > 1 gm/L. Both parameters were checked and were abnormal on at least two random occasions, 6 hours apart.

Chronic hypertension with superimposed severe preeclampsia. This group was made up of seven patients aged 28 to 41 years (35 ± 4) with hypertension developing before the twentieth week of pregnancy and later development of a severe preeclamptic state. In all these patients hypertension remained for at least 40 days after delivery.

Table I shows some clinical and analytic data on these groups. None of the patients in the preeclampsia groups showed substantial alterations in the levels of hepatic enzymes. The control group for patients with

preeclampsia was the group of normal pregnant women in the third trimester of pregnancy. Normal plasma was pooled from 24 apparently healthy men with no history of bleeding or thrombosis. Informed consent was obtained from all patients and control subjects before blood collection.

Venous blood samples were obtained from the cubital vein in 1:9 (vol/vol) 0.11 mol/L trisodium citrate with or without 50 mmol/L benzamidine (Sigma Chemical Co., St. Louis), and plasma samples were stored in aliquots at −70° C.

Assays. Protein C antigen and activity[16] and protein C inhibitor antigen and activity[17] were assayed as previously described. Activated protein C/protein C inhibitor[17] and activated protein C/α_1-antitrypsin[18] complexes were determined by sandwich enzyme-linked immunosorbent assay as described before. Briefly, activated protein C complexes were assayed by coating plates with a monoclonal anti–protein C antibody, and complexes of activated protein C bound to the plates were detected with peroxidase-labeled rabbit anti–protein C inhibitor and anti-α_1-antitrypsin antibodies, respectively. The detection limit for activated protein C/protein C inhibitor and activated protein C/α_1-antitrypsin assays was 3 and 1 ng/ml, respectively. Calibration curves were constructed with known amounts of purified preformed activated protein C complexes. Blood for activated protein C complex assays was anticoagulated with citrate containing 50 mmol/L benzamidine.

α_1-Antitrypsin was measured by rocket immunoelectrophoresis with a commercial rabbit antiserum against human α_1-antitrypsin (Sigma) in 1% agarose in Tris-glycine buffer (0.038 mol/L Tris, 0.1 mol/L glycine, 2.1 mmol/L ethylenediaminetetraacetate, and 0.02% sodium azide, pH 8.7) with 0.46% (vol/vol) antiserum. Plasma was diluted 1:200 in Tris-glycine buffer, and 12 μl of the diluted plasma was applied to sample wells. Electrophoresis at 8 mA (15 v/cm) was carried out overnight at room temperature. The gels were washed twice for 2 hours in 0.5 mol/L saline solution and then twice in distilled water; immunoprecipitates were visualized with Coomassie Brilliant Blue R-250.

Because of the normal distribution of data, changes in the levels of activated protein C/α_1-antitrypsin complex, protein C inhibitor, α_1-antitrypsin, and protein C throughout pregnancy were subjected to computerized analysis of variance. The level of activated protein C/protein C inhibitor complex in normal and pathologic pregnancy was compared with the χ^2 test, and Yates' correction was applied when necessary. The Student *t* test was used for comparison between pathologic pregnancy groups and the third trimester of pregnancy.

Results

The level of activated protein C/α_1-antitrypsin complex in plasma samples of pregnant women at different gestational ages was compared with that of nonpregnant control subjects (Fig. 1). The pregnant women showed mean complex levels of 9 ± 4 ng/ml (mean ± SD) (first trimester), 12 ± 3 ng/ml (second trimester), and 16 ± 3 ng/ml (third trimester), whereas the nonpregnant women had a mean complex level of 8 ± 3 ng/ml, with a range of 3 to 14 ng/ml; the difference between nonpregnant and pregnant women in the second and third trimesters of pregnancy was significant at the $p < 0.001$ level. There was a good correlation between activated protein C/α_1-antitrypsin complex levels and weeks of gestation ($r = 0.636$, $p < 0.001$). The severe preeclampsia group showed a marked increase in the level of activated protein C/α_1-antitrypsin complex (29 ± 9 ng/ml, $p < 0.001$) compared with that of normal pregnant women in the third trimester of pregnancy. In contrast, the group of pregnant women with chronic hypertension and superimposed severe preeclampsia had an activated protein C/α_1-antitrypsin complex level (15 ± 6 ng/ml) that was similar to that of the control group of women in the third trimester of pregnancy.

The level of activated protein C/protein C inhibitor complexes in all groups is seen in Fig. 2. All plasma samples from nonpregnant women had levels below the detection limit of the assay used (<3 ng/ml). Of 78 normal pregnant women studied, detectable activated protein C/protein C inhibitor complex levels were found in only four women. Seven of the 14 patients with severe preeclampsia had detectable levels ranging between 7 and 21 ng/ml (median, 13 ng/ml), and only one of the seven patients with chronic hypertension with superimposed severe preeclampsia had a detectable level of 20 ng/ml. The difference between the levels in normal pregnant women and those with severe preeclampsia was significant at $p < 0.001$. However, no significant differences were observed between the levels in normal pregnant women and those found in chronic hypertension with superimposed severe preeclampsia. In patients with a positive activated protein C/protein C inhibitor complex, there was a good correlation between activated protein C/α_1-antitrypsin and activated protein C/protein C inhibitor complex levels ($r = 0.619$, $p < 0.05$).

To assess whether the difference between the levels of activated protein C/α_1-antitrypsin and activated protein C/protein C inhibitor observed both in normal pregnancy and in pathologic pregnancy is due to changes in the levels of protein C inhibitor or α_1-antitrypsin, the activated protein C serine protease inhibitors were measured in all groups. The functional

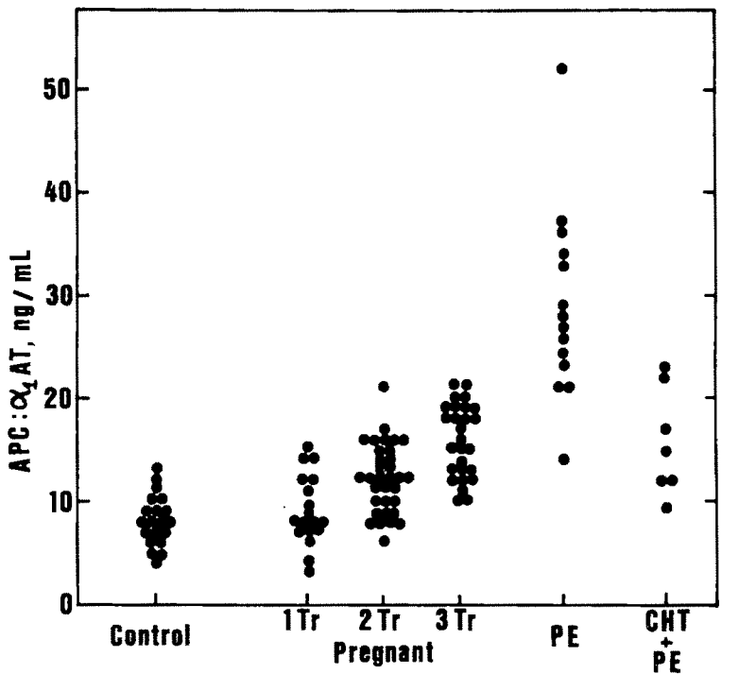

Fig. 1. Activated protein C/α_1-antitrypsin *(APC : α_1AT)* complex levels in control nonpregnant women (n = 20), in women with normal pregnancy during the first *(1 Tr,* n = 18), second *(2 Tr,* n = 33), and third trimesters *(3 Tr,* n = 27), in severe preeclampsia *(PE,* n = 14), and in chronic hypertension with superimposed severe preeclampsia *(CHT + PE,* n = 7). Activated protein C/α_1-antitrypsin complex levels in pregnant women at second and third trimesters were significantly higher ($p < 0.001$) than those of controls. The activated protein C/α_1-antitrypsin complex level in severe preeclampsia, but not in chronic hypertension with superimposed severe preeclampsia, was significantly higher ($p < 0.001$) than that of women in the third trimester.

and antigenic protein C inhibitor levels of pregnant women at different gestational ages were compared with those of nonpregnant controls (Table II). The pregnant women showed a mean functional protein C inhibitor level of 86% ± 15% (mean ± SD) (first trimester), 82% ± 12% (second trimester), and 77% ± 18% (third trimester). The nonpregnant women had a mean functional protein C inhibitor level of 96% ± 21% with a range of 62% to 139%; the difference between these levels and those of the three groups of pregnant women was significant at the $p < 0.05$ (first trimester), $p < 0.01$ (second trimester), and $p < 0.001$ (third trimester) levels. The group with severe preeclampsia showed a significantly decreased mean functional protein C inhibitor level (63% ± 26%, $p < 0.01$) as compared with that of normal pregnant women in the third trimester of pregnancy, whereas the group with chronic hypertension with superimposed severe preeclampsia had an increased level of functional protein C inhibitor (91% ± 16%, $p < 0.05$) as compared with the control group of women in the third trimester of pregnancy. Protein C inhibitor antigen levels were similar to functional protein C inhibitor levels in all groups except in the third trimester of pregnancy, in which the functional protein C inhibitor level was significantly reduced as compared with the antigen protein C inhibitor level ($p < 0.05$).

The values of α_1-antitrypsin in normal and pathologic pregnancy and in the nonpregnant control group are seen in Table II. The nonpregnant women had a mean α_1-antitrypsin level of 96% ± 9% with a range of 78% to 130%. The mean α_1-antitrypsin levels of pregnant women increased during pregnancy and were significantly increased (139% ± 29%, first trimester; 143% ± 16%, second trimester; 158% ± 24%, third trimester) as compared with that of the nonpregnant women at the $p < 0.001$ level. Both the group with severe preeclampsia and the group with chronic hypertension and superimposed severe preeclampsia had similar α_1-antitrypsin levels (164% ± 35% and 156% ± 19%, respectively) as compared with those of the control group of normal pregnant women in the third trimester of pregnancy.

Protein C, both antigen and amidolytic activity, also was measured in all groups (Table II). No significant alterations were found in the level of protein C during

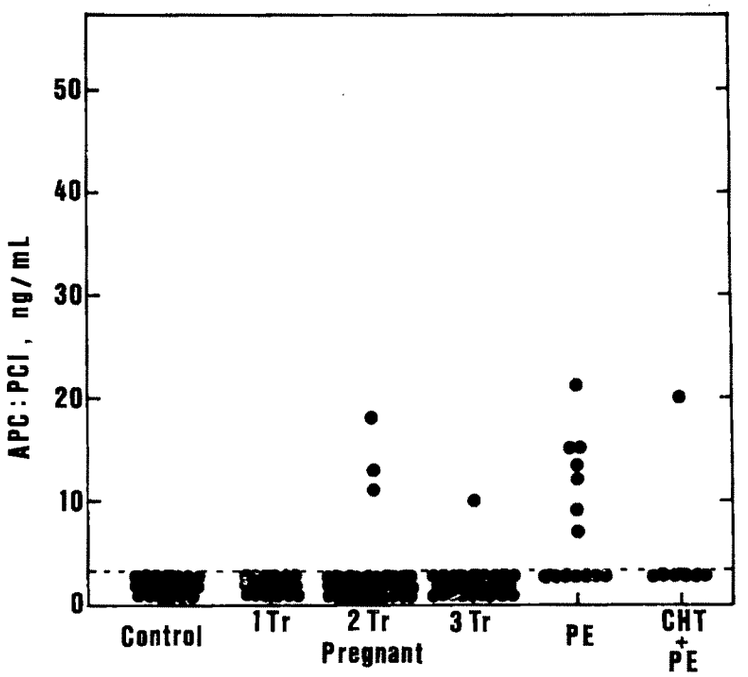

Fig. 2. Activated protein C/protein C inhibitor *(API:PCI)* complex levels in controls and in normal and pathologic pregnancies. Groups are same as in Fig. 1. Difference between complex levels in women with normal pregnancy and women with severe preeclampsia was significant at $p < 0.001$.

Table II. Coagulation parameters in controls (nonpregnant women), in normal pregnancy during first, second, and third trimesters, in patients with severe preeclampsia, and in patients with chronic hypertension and superimposed severe preeclampsia

	No. of patients	*Protein C (%)*		*Protein C inhibitor (%)*		
		Antigen	*Functional*	*Antigen*	*Functional*	*α_1-Antitrypsin (%)*
Controls (nonpregnant)	20	98 ± 16	95 ± 14	98 ± 16	99 ± 18	96 ± 9
Normal pregnancy

normal pregnancy, whereas functional protein C was significantly decreased in severe preeclampsia as compared with the levels of the normal pregnant women at a similar gestational age (third trimester). In contrast, patients with chronic hypertension with superimposed severe preeclampsia showed protein C values similar to those of normal pregnant controls.

Comment

Our results show a progresive increase in activated protein C/α_1-antitrypsin complex level during normal pregnancy, reaching values twice that of the control group in the third trimester (Fig. 1), i.e., 16 versus 8 ng/ml. In contrast, only 5% of the pregnant women had detectable levels of activated protein C/protein C

inhibitor complex (Fig. 2). These relative amounts of the two activated protein C complexes seen in pregnancy are similar to those found in patients with thrombotic disease[19] and do not coincide with in vitro[8] and in vivo[9, 19] data suggesting that the two types of activated protein C complexes are formed at approximately the same rate. One possibility is that in vivo, activated protein C/protein C inhibitor is cleared faster than activated protein C/α_1-antitrypsin as indeed is the case in baboons.[19a] Another possibility is the presence of hitherto unrecognized in vivo factors that modulate the relative rates of complex formation.

The group of patients with severe preeclampsia showed a significant increase in the level of activated protein C/α_1-antitrypsin as compared with normal women in the third trimester of pregnancy and with patients with chronic hypertension and superimposed severe preeclampsia, whereas the group of patients with chronic hypertension and superimposed severe preeclampsia had activated protein C/α_1-antitrypsin levels similar to those in the third trimester of pregnancy. This likely reflects basic differences in pathogenic mechanisms between severe preeclampsia and chronic hypertension with superimposed severe preeclampsia.

To ascertain whether the increase in the levels of activated protein C/inhibitor complexes was the result of a variation in the levels of the inhibitors, we measured the protein C inhibitor and α_1-antitrypsin levels in all groups. Although there is a significant increase in the α_1-antitrypsin levels in pregnancy, no correlation between levels of activated protein C/α_1-antitrypsin and those of α_1-antitrypsin was found in any of the groups studied. Moreover, the α_1-antitrypsin levels of patients with severe preeclampsia were similar to those of the group with chronic hypertension with superimposed severe preeclampsia and those of the control group in the third trimester, but the level of activated protein C/α_1-antitrypsin complex in patients with severe preeclampsia was twice that of the two other groups. These data suggest that the increase in the level of activated protein C/α_1-antitrypsin complex during pregnancy and in severe preeclampsia is not due, or at least not principally due, to the increase in the level of α_1-antitrypsin. Rather, it may reflect greater activation of the protein C system that is due in turn to greater thrombin activity. Moreover, activation of the intrinsic coagulation pathway has been reported to occur in preeclampsia.[20] As a result, kallikrein is generated that could interact with protein C inhibitor, resulting in protein C inhibitor inactivation[18, 21] and making α_1-antitrypsin the major inhibitor of activated protein C. In fact, we found significantly decreased levels of protein C inhibitor activity and antigen in preeclampsia (Table II).

In summary, our results support the hypothesis that a hypercoagulable state exists in both normotensive and hypertensive pregnant patients and that the increased levels of thrombin result in an overactivation of the protein C pathway. Evidence for this prethrombotic state in normal pregnancy and in preeclampsia was also provided by Wallmo et al.[22] and Weiner et al.[22] who reported a significant rise in fibrinopeptide A levels in pregnancy[22, 23] and in preeclampsia,[22] and by de Boer et al.[24] who found increased thrombin–antithrombin III levels in normal and hypertensive gestations. Our results also support previous suggestions[18, 19] that the activated protein C/α_1-antitrypsin complex could be a suitable marker for specific detection of activation of the clotting and protein C pathways. Activated protein C/α_1-antitrypsin could also aid in the differential diagnosis of severe preeclampsia versus chronic hypertension with superimposed severe preeclampsia and represents a reasonable initial screening for the coagulation abnormalities accompanying preeclampsia.

We thank Mrs. Josefa Solano for her excellent technical assistance.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1991 issues from the Publisher, at a cost of $61.00 for domestic, $88.27 for Canada, and $84.00 for international for Vol. 164 (January-June) and Vol. 165 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Progress in pathogenesis and management of clinical intraamniotic infection

Ronald S. Gibbs, MD,[a] and Patrick Duff, MD[b]
Denver, Colorado, and Gainesville, Florida

In the past decade, gratifying progress has been achieved in our understanding of clinical intraamniotic infection. With a usual incidence of 1% to 4%, clinical intraamniotic infection mainly develops as an ascending prccess after prolonged rupture of the membranes and labor, but other cases may be hematogenous in origin whereas still others complicate intrauterine procedures. The most common organisms isolated in amniotic fluid of cases of intraamniotic infections are anaerobes, genital mycoplasmas, group B streptococci, and *Escherichia coli.* The latter two are found most commonly in maternal or neonatal bacteremia complicating intraamniotic infection. Although the diagnosis remains largely a clinical one, laboratory tests have been suggested to confirm the diagnosis in women with symptoms. These include amniotic fluid Gram stain, gas-liquid chromatography, and leukocyte esterase measurement. Maternal treatment consists of antibiotic therapy and delivery. Studies to date have used a penicillin plus an aminoglycoside, with some authors advocating the addition of clindamycin after cesarean delivery. Other broad-spectrum regimens may be equally effective. Complications of clinical intraamniotic infections include an increase in cesarean section rate and in maternal and neonatal bacteremia. Poor neonatal outcomes in intraamniotic infection are more likely in the following cases: (1) when *E. coli* or group B streptococci are present in the amniotic fluid; (2) when the infant has a low birth weight; (3) when maternal antibiotic therapy is delayed until after delivery. (Am J Obstet Gynecol 1991;164:1317-26.)

Key words: Clinical intraamniotic infection, prolonged rupture of membranes, antibiotic therapy

Clinical intraamniotic infection is a common, acute, clinically detectable infection primarily of the uterus and its contents during pregnancy. Extragenital manifestations include bacteremia and shock. Several alternative terms are in widespread use and include *clinical chorioamnionitis, amnionitis, amniotic fluid infection,* and *intrapartum infection.* (In this review we use the term given by the original authors.)

Intraamniotic infection is distinct, however, from histologic chorioamnionitis, a condition defined histopathologically by the presence of polymorphonuclear infiltrates in the placenta and its membranes. Histologic chorioamnionitis occurs far more frequently than does clinically evident intraamniotic infection. At term, histologic chorioamnionitis occurs in approximately 20% of pregnancies but is infrequently associated with clinically evident intraamniotic infection. Before term, histologic chorioamnionitis occurs much more frequently, recently being reported as high as 60% in pregnancies with birth weights between 1000 and 1500 gm.[1]

Definition of intraamniotic infection

The diagnosis of intraamniotic infection has in general been based on fever, usually with membrane rupture, and a variety of other physical and laboratory findings. For the purposes of their prospective studies, Gibbs et al.[2] defined intraamniotic infection on the basis of temperature ≥100° F (37.8° C) plus two or more of the following conditions: maternal tachycardia, fetal tachycardia, uterine tenderness, foul odor of the amniotic fluid, or maternal leukocytosis. (Because these studies involved exclusively patients who had amniotic fluid samples aspirated by intrauterine pressure catheter, all of the patients also had ruptured membranes.)

Incidence

In the past the overall incidence of this condition was reported as being approximately 1% to 2%. In a ret-

rospective study in 1980 Gibbs et al.[3] reported an incidence of 0.8% in a teaching hospital in San Antonio. Koh et al.[4] at Los Angeles County Hospital reported a similar incidence at approximately the same time.

Two recent prospective studies,[5, 6] also at teaching hospitals, reported higher incidences, 4.2% and 10.5%, respectively. It is unclear whether the incidence has truly increased over the past decade, perhaps because of increased use of invasive techniques during labor, or whether the older rates underestimated the true occurrence of the disease.

Pathogenesis

Most cases of intraamniotic infection are ascending in origin, commonly after prolonged rupture of the membranes and labor in patients with multiple examinations. However, occasionally intraamniotic infection may occur in patients with labor but without membrane rupture.

A second route of intraamniotic infection is hematogenous spread in mothers with bacteremia. Most notably, *Listeria monocytogenes*, which may occur either as an epidemic or in isolated cases, has been reported as a cause of blood-borne intraamniotic infection.[7] In addition, there have been cases of hematogenous intraamniotic infection caused by group A streptococci and *Campylobacter* sp.[8]

A third mechanism for the development of intraamniotic infection is introduction of bacteria during an invasive procedure. After diagnostic amniocentesis, the risk of acute intraamniotic infection is low, probably best estimated as 1 in 1000.[9] With more extensive manipulations, such as intrauterine transfusions, the risk of acute infection may be estimated as high as 5%.[10] Intraamniotic infection also may be a complication of cervical cerclage. Most studies indicate that the likelihood of intrauterine infection after placement of a cervical cerclage is in the range of 1% to 2%,[11] but in patients who have a cerclage placed after marked dilatation and prolapse of the membranes into the vagina, the risk of intrauterine infection may be as high as 25%.[12] Percutaneous umbilical blood sampling has occasionally been the cause of fetal loss (1.4%, 36/2501), but approximately half of the losses (n = 17) are due to chorioamnionitis (Berkowitz R. North American Periumbilical Blood Sampling Registry. Presented at the Thirty-seventh Annual Meeting of the Society for Gynecologic Investigation, St. Louis, Missouri, March 21-24, 1990).

Coitus during pregnancy has been suggested as a risk factor for *amniotic fluid infection*.[13] However, Mills et al.[14] in a study of 10,000 Israeli women demonstrated that frequency of intercourse decreased during pregnancy, from >90% of women in the first 6 months to 36% of women in the ninth month, and that women who had intercourse did not have an increased risk of premature rupture of the membranes, low birth weight, or perinatal death.

In 1989 two prospective, sophisticated studies of risk factors for intraamniotic infection appeared. At the Medical College of Virginia, Soper et al.[6] prospectively evaluated 408 women for chorioamnionitis. Newton et al.[5] in San Antonio evaluated 2908 women. With an overall incidence of 10.5% and 4.2%, respectively, in these two studies, independent risk factors were identified by logistic regression. These are shown in Table I. With their logistic regression model, Newton et al.[5] were able to develop probability curves that are based on parity, duration of internal fetal monitoring, and duration of ruptured membranes, as shown in Fig. 1, which shows a curve that was developed for nulliparous women. In this model the probability of intraamniotic infection was estimated at 20% in patients who had 20 hours of membrane rupture and 3 hours of internal fetal monitoring. However, the risk of intraamniotic

infection rose to an estimated 40% in patients who had 20 hours of membrane rupture and internal fetal monitoring of 12 hours. It was also important to note from this study that most patients entered a high-risk category a number of hours before development of clinically evident intraamniotic infection. This observation suggests that it might be possible to implement intervention strategies to prevent clinically evident intraamniotic infection.

More than 35 years ago, investigators recognized that amniotic fluid may contain substances that inhibit bacterial growth. In the late 1960s and the 1970s a number of groups identified various amniotic fluid antibacterial factors. Most notably, the group at the University of Iowa[15] reported isolation of a low-molecular-weight peptide with a zinc cofactor that inhibited bacterial growth. Subsequently, Blanco et al.[16, 17] reported that amniotic fluid from patients with intraamniotic infection was significantly less likely to inhibit the growth of *Escherichia coli* and group B streptococci.

However, when Silver et al.[18] subsequently attempted to isolate a specific amniotic fluid bacterial inhibitor, they were not able to demonstrate any bacterial inhibitory property of amniotic fluid once they corrected for the major effect of pH and a minor effect of osmolality. At present, it is unclear whether there are specific bacterial inhibitors in amniotic fluid and whether these are clinically relevant.

Microbiology

The microbiologic composition of amniotic fluid in patients with intraamniotic infection is indeed complex and is similar to that of several other obstetric infections. In 1982, Gibbs et al.[19] published a case-control study of the microbiologic features of amniotic fluid in 52 patients who had clinically evident intraamniotic infection and in 52 matched, case controls. Seventy percent of the patients with intraamniotic infection had $\geq 10^2$ CFU/ml of virulent organisms, but in comparison only 8% of patients in the control group had this finding ($p < 0.001$). The most common organisms in patients with intraamniotic infection in this series were anaerobes and group B streptococci. The next year, this group[20] reported that *Mycoplasma hominis* was present in the amniotic fluid of 35% of patients with intraamniotic infection and in only 8% of matched controls ($p < 0.001$), whereas *Ureaplasma urealyticum* was present in 50% of patients in both groups. Most patients who had *M. hominis* in the amniotic fluid also had $>10^2$ CFU/ml of virulent organisms (83%, 15/18). In 1982 Gravett et al.[21] reported similar findings in a smaller series. In 1988 the results of amniotic fluid culture in 408 cases of intraamniotic infection were summarized[22] (Table II).

Recently, interesting interactions of organisms in the amniotic fluid of these cases became apparent. Two constellations of organisms were noted.[23] In one, *Gardnerella vaginalis, M. hominis,* and anaerobes appeared to be associated with each other in the amniotic fluid. When one of these organisms was present in the amniotic fluid, it was significantly more likely that another member of this constellation also would be present. In the second set of interactions between organisms, enterococci, *E. coli,* and other aerobic gram-negative rods were associated. These patterns of organisms in the amniotic fluid suggested that in the former group bacterial vaginosis–associated organisms might be the source, whereas in the latter series gut-associated organisms might be the source.

Table II. Distribution of microbes in 408 cases of intraamniotic infection[22]

Microbe	*No.*	*%*
Group B streptococci	60	15
Enterococci	22	5
E. coli	33	8
G. vaginalis	99	24
Other aerobic gram-neg. rods	21	5
Peptostreptococci	38	9
B. bivius	120	29
Fusobacterium sp.	23	6
B. fragilis	14	3
M. hominis	125	31
U. urealyticum	193	47

When patients with intraamniotic infection were stratified by birth weights of their infants, we found that pregnancies resulting in low-birth—weight infants (<2500 gm) were more likely to have anaerobes in the amniotic fluid.[22] For example, *Bacteroides bivius* was present in 45.9% of pregnancies with low-birth-weight infants and in 27.9% of pregnancies with non-low-birth-weight infants ($p = 0.035$). Similarly, *Fusobacterium* sp. were present in 21.6% of low-birth-weight pregnancies compared with just 3.8% of non-low-birth-weight pregnancies ($p < 0.001$). It was of interest that there was no difference in the isolation rate of group B streptococci, *E. coli,* or other aerobic organisms or of *M. hominis* or *U. urealyticum.* These data may be interpreted to imply that subclinical anaerobic infection may cause preterm labor or preterm premature rupture of the membranes, in the first place, and then are more likely to be isolated in pregnancies with low-birth-weight infants and clinically evident intraamniotic infection.

Because of the multiplicity of organisms found in the amniotic fluid of patients with intraamniotic infection, serologic studies have been performed to help in the understanding of pathogenicity. Using an enzyme-linked immunosorbent assay for detection of maternal serum antibody, Gibbs et al.[24] found that women who have intraamniotic infection with *M. hominis* in the amniotic fluid have a significantly greater antibody re-

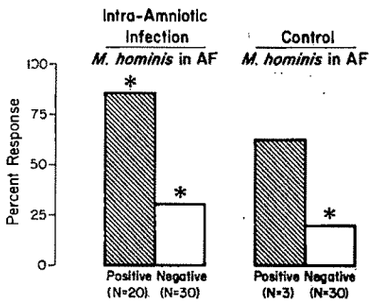

Fig. 2. Antibody response to *M. hominis* (seroconversion and/or rise in A_{400} [absorbance] >0.2) in patients with intraamniotic infection and in control patients. Women with intraamniotic infection and *M. hominis* in amniotic fluid had an antibody response significantly more often than did other groups (*asterisk*, $p < 0.05$) (see ref. 19).

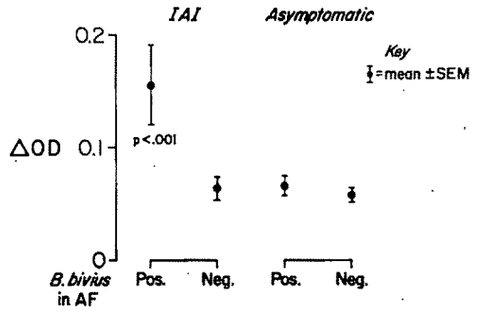

Fig. 3. Antibody response by enzyme-linked immunosorbent assay to *B. bivius* in patients with intraamniotic infection and in control patients. Mean duration of delivery was significantly greater in women with intraamniotic infection and *B. bivius* in amniotic fluid than in any other group (on basis of data in ref. 24).

sponse than do appropriate control subjects (Fig. 2). We observed similar significant antibody changes in patients who had intraamniotic infection and with *B. bivius* in the amniotic fluid (Fig. 3).[25] These serologic studies indicate that these organisms, among others, most likely are pathogenic in intraamniotic infection. On the other hand, no significant antibody changes were identified for either *G. vaginalis* or *Chlamydia trachomatis*.[26, 27]

Even though group B streptococci and *E. coli* are present collectively in only 20% of amniotic fluid samples from women with intraamniotic infection, these two organisms account for 67% of either maternal or neonatal bacteremia.[22, 23] As shown in Table III, when group B streptococci are present in the amniotic fluid from cases of intraamniotic infection, either the mother or the neonate has group B streptococcal sepsis in 25% of cases. With *E. coli* in the amniotic fluid of these cases, bacteremia develops in 33% of maternal-infant pairs. Among 408 cases of intraamniotic infection, organisms causing maternal bacteremia were as follows: group B streptococci ($n = 11$), *E. coli* ($n = 7$), *Staphylococcus aureus* ($n = 2$), *Listeria monocytogenes* ($n = 2$), *Bacteroides* sp. ($n = 2$), and one each with enterococci, viridans streptococci, *Streptococcus pneumoniae*, and *Pseudomonas aeruginosa*.[23] Bloodstream isolates from newborns in these cases were as follows: group B streptococci ($n = 4$), *E. coli* ($n = 5$), *S. aureus* ($n = 2$), streptococci ($n = 3$), enterococci ($n = 2$), *Enterobacter* sp. ($n = 1$), *Haemophilus influenzae* ($n = 1$), *Haemophilus parainfluenzae* ($n = 1$), and microaerophilic streptococci ($n = 1$).[22] Of note, no cases of anaerobic neonatal bacteremia were documented, and there were only two cases of maternal anaerobic bacteremia. This observation may be interpreted to mean that the anaerobes are active locally but are not invasive organisms. It has also been suggested that current techniques may not be able to detect anaerobic bacteremia, especially with low inoculum size.

Clinical and laboratory diagnosis

Clinical criteria used to make the diagnosis of intraamniotic infection are fever, maternal tachycardia, fetal tachycardia, uterine tenderness, and foul odor of the amniotic fluid, all with or without membrane rupture. Since most patients do not have all of these findings, laboratory tests may assist in making the diagnosis. Of these laboratory measures, maternal peripheral blood leukocyte count is the most readily available. In patients with symptoms several investigators over the past decade have evaluated rapid diagnostic techniques, including amniotic fluid Gram stain (Fig. 4), amniotic fluid gas-liquid chromatography, and amniotic fluid leukocyte esterase.

Maternal leukocytosis. Patients with clinical intraamniotic infection often have a moderate leukocytosis (>12,000/mm³ to 15,000/mm³) with a shift toward more immature cell forms ("left shift"). In a case-control study Gibbs et al.[2] reported leukocytosis (>15,000/mm³) in 63% of cases of intraamniotic infection and in 21% of matched controls. Hoskins et al.[28] found leukocytosis (>12,000/mm³) to be a test with 67% sensitivity, 86% specificity, 82% positive predictive value, and 72% negative predictive value.

Gram stain and culture of amniotic fluid. Gram stain and culture of amniotic fluid are of value in confirming the diagnosis of chorioamnionitis in patients with symptoms,[2] when amniotic fluid usually is obtained through the intrauterine pressure catheter. A positive Gram stain was defined as the presence of any bacteria in a high-power oil-immersion field[2] of uncentrifuged amniotic fluid. White blood cells may be present in amniotic fluid simply as a consequence of labor, and thus they are not necessarily indicative of infection. In this

Table III. Outcomes by organism in amniotic fluid[22, 23]

Organism	*Neonatal sepsis*	*Neonatal death from sepsis*	*Maternal sepsis*	*Maternal or neonatal sepsis*
Total (N = 408)	19 (5%)	4 (1%)	23 (6%)	39 (10%)
Group B streptococci (n = 60)	4 (7%)	2 (3%)	11 (18%)*	15 (25%)*
E. coli (n = 33)	6 (18%)	1 (3%)	5 (15%)*	11 (33%)*
Anaerobes (n = 178)			2 (1%)	2 (1%)

*$p < 0.05$, Compared with overall group.

case-control study organisms were observed in 67% (35/52) of cases of intraamniotic infection versus only 12% (6/52) of controls ($p = 0.001$). Forty-two (81%) cases of intraamniotic infection had detectable leukocytes on direct smear whereas only 15 (29%) control cases had this finding ($p < 0.001$).[2]

Leukocyte esterase assay of amniotic fluid. Polymorphonuclear leukocytes contain several esterase enzymes that are not present in serum, urine, or other body fluids. Recently, a simple chemical test for the presence of one of these enzymes has been developed. The leukocyte esterase reagent strip (Boehringer Mannheim, Indianapolis) identifies the esterase that catalyzes the hydrolysis of an indoxyl carboxylic acid ester to indoxyl. Esterase activity can be measured in the absence of intact cells and is not affected by changes in pH, protein concentration, or bacterial content of the fluid specimen. Hoskins et al.[28] evaluated the leukocyte esterase reagent strip in 21 patients with suspected chorioamnionitis and 21 control subjects without symptoms. Amniotic fluid was aspirated through the intrauterine pressure catheter in all patients. Using the clinical diagnosis of chorioamnionitis as the standard for comparison, the authors found that the leukocyte esterase test showed excellent sensitivity (91%), specificity (95%), and positive and negative predictive values (95% and 91%, respectively).

Gas-liquid chromatography. Gravett et al.[21] were the first to describe the use of gas-liquid chromatography for the diagnosis of chorioamnionitis. They evaluated 16 women with clinical evidence of intrapartum infection and 22 control patients without symptoms. Amniotic fluid was collected from patients by transabdominal amniocentesis, aspiration through the intrauterine pressure catheter, or needle aspiration at the time of cesarean delivery. Gas-liquid chromatography was used to identify organic acids in the amniotic fluid specimens. All amniotic fluid samples contained lactate, which is a recognized byproduct of fetal metabolism. Other organic acids were identified in only one of 22 control specimens, in comparison with 15 of 16 samples from patients with infection ($p < 0.0005$). The authors concluded that acids other than lactate (such as acetate, propionate, and butyrate) were products of bacterial metabolism and that identification of these substances was a highly sensitive and specific test for confirmation of chorioamnionitis.

In spite of the impressive results achieved by Gravett et al., several caveats must be emphasized. First, the instrument that the authors used was equipped with a flame ionization detector that was able to detect minute quantities of organic acids. Not all gas-liquid chromatographs are equally sensitive. Second, such sophisticated instrumentation is not readily available at every hospital, especially during evening and nighttime hours. Third, the test is labor intensive and relatively expensive. Therefore for all of the reasons outlined here gas-liquid chromatography analysis is not a test that can be used routinely for diagnosis of intraamniotic infection. The test appears to have its greatest application in research studies designed to investigate microbiologic and pathophysiologic characteristics.

Histologic examination of placental membranes. Histologic examination of the membranes is of limited value in the anterospective diagnosis of intraamniotic infection. First, in the patient whose infant has not been delivered, biopsy of the chorioamniotic membranes currently is neither practical nor safe. Second, even if the biopsy could be performed safely, the processing of the tissue specimen for histologic examination is relatively expensive and labor intensive. Personnel skilled in histologic interpretation are not likely to be available at all hours of the day and night. Third, the histologic inflammation occurs much more commonly than does the clinical syndrome of chorioamnionitis. In high-risk populations nearly all cases of clinical intraamniotic infection have histologic inflammation in the membranes,[29] yet histologic chorioamnionitis is seen in 11% of all membranes and in >50% of membranes from pregnancies with birth weights <1000 gm,[30] whereas clinical chorioamnionitis is diagnosed much less frequently (usually 0.8% to 4%).[3-5]

Immediate outcome

Older retrospective studies of outcome after intraamniotic infection[3, 4, 31, 32] are summarized in Table IV. In summary, these studies demonstrated that intraam-

Fig. 4. Gram stain of uncentrifuged amniotic fluid from patient with intraamniotic infection, showing numerous gram-positive cocci.

niotic infection was accompanied by a twofold to threefold increase in cesarean section rate. Further, with the mean interval from diagnosis of intraamniotic infection to delivery being 3 to 7 hours, no "critical interval" was noted (i.e., after which maternal or neonatal complications increased).[32] Although perinatal mortality was reported to increase in cases of intraamniotic infection, little of the excess perinatal mortality was directly due to infection and the major contributor to high perinatal mortality was prematurity itself.

Effect on labor. More recent studies have addressed the effect of intraamniotic infection on labor and the effects of birth weight and timing of antibiotics on outcome.

In subsequent studies by Duff et al.[33] and Silver et al.,[34] labor in patients who had clinically evident intraamniotic infection and subclinical infection, respectively, was characterized. Patients with clinically evident intraamniotic infection were most often primigravid with dystocia. Approximately 80% had been receiving oxytocin at the time of diagnosis of intraamniotic infection, and abnormal fetal heart rate patterns were fairly common.[31] Even patients without symptoms but with positive amniotic fluid cultures (suggested by the authors to be "subclinical intraamniotic infection") appeared to require a higher dose of oxytocin to achieve adequate uterine activity.[34] Even with adequate uterine activity, progress in cervical dilatation was slow. Since this abnormal cervical dilatation could not be explained by excessive fetal size, an abnormal pelvis, anesthetics, or other drugs, the authors speculated that infection per se may have some adverse effect on cervical collagen tissue.

Effect of birth weight. Recent controlled studies have demonstrated that intraamniotic infection in pregnancies with low-birth-weight infants is much more likely to result in poor outcome, when compared with non-infected pregnancies at the same gestational age or infected pregnancies at term. In 1982 Garite and Freeman[35] compared pregnancies with and without amnionitis at 28 to 34 weeks' gestation. There was a significant increase in perinatal deaths, respiratory distress syndrome, and total infections in 47 pregnancies with amnionitis as compared with the 204 cases without amnionitis. Ferguson et al.[36] reported a case-control study of perinatal outcome after *chorioamnionitis* in 1985. More than 70% of their cases were in low-birth-weight infants. Although the differences were not statistically significant, the chorioamnionitis cases were accompanied by a higher perinatal mortality rate (20% vs 11%), a higher sepsis rate (6% vs 2%), and a higher asphyxia rate (27% vs 16%). Since all of these adverse effects were higher in the group with chorioamnionitis, we suspect that there may be a substantial β-error in this study in that true adverse effects are not detected. The recent work by Morales,[37] studying 92 patients with chorioamnionitis and 606 control cases of similar gestational ages, also demonstrates significant increases in the group with chorioamnionitis in mortality, respiratory distress syndrome, intraventricular hemorrhage, and clinically diagnosed sepsis (see Table V).

Sperling et al.[22] compared outcome characteristics in cases of intraamniotic infection leading to low-birth-weight infants versus infants of normal weight. The outcome in the former group was characterized by more frequent maternal bacteremia (13.5% vs 4.9%, $p = 0.06$), early onset neonatal sepsis (16.2% vs 4.1%, $p = 0.005$), and neonatal death from sepsis (10.8% vs 0%, $p < 0.001$). Among low-birth-weight infants the interval from rupture of membranes to a diagnosis of intraamniotic infection was short when anaerobes only were isolated in the amniotic fluid compared with when aerobes only were isolated in the amniotic fluid (mean ± SD, 3.8 ± 5.4 vs 39.2 ± 28.3 hours; $p \leq 0.001$). One may interpret these data to show that the significantly shorter interval of low-birth-weight infants with anaerobes in the amniotic fluid suggests that anaerobic intraamniotic infection may have preceded preterm premature rupture of the membranes.

Taken as a whole, these studies clearly demonstrate the adverse effects of intraamniotic infection in pregnancies with low-birth-weight infants.

Selection and timing of antibiotics. In broad principle there is agreement that patients who have acute intraamniotic infection need the general support of therapy, that antibiotic therapy is appropriate, and that delivery is essential to a cure. (There have been a few reported cases of subclinical chorioamnionitis that were cured without delivery.[38] However, in clinically evident disease protraction in delivery may lead to serious, life-threatening maternal infection.) For several decades there was debate as to when antibiotics should be ad-

Table IV. Retrospective studies of outcome after intraamniotic infection

*Interval from diagnosis of intraamniotic infection to delivery.

ministered. Some favored intrapartum treatment begun promptly to protect the mother from complications such as septicemia and shock. Others argued for delaying treatment until after delivery so that "more thorough cultures of the neonate" might be obtained. Although no agreement exists as to the standard antibiotic selection for intraamniotic infection, most studies to date (both retrospective and prospective) have evaluated a penicillin, usually ampicillin, often in combination with an aminoglycoside. In view of the high failure rate of the ampicillin-aminoglycoside combination in patients with chorioamnionitis *and* cesarean section, we have advocated the empiric addition of clindamycin after cord clamping. Although no studies have been published, it is possible that other regimens may be equally effective. Considering the spectrum of organisms involved in intraamniotic infection, we suspect that several of the newer penicillins, cephalosporins, or penicillin plus β-lactamase inhibitor combinations may be highly successful.

Within the past decade there also has been rising interest among neonatologists in treating early onset neonatal sepsis or meningitis with combination antibiotics other than ampicillin plus gentamicin.[39] These alternative regimens include ampicillin plus a newer, cephalosporin-like antibiotic, such as cefotaxime or ceftriaxone. Similar regimens also may be reasonable in the treatment of intraamniotic infection because they may offer pharmacokinetic advantages over gentamicin and may obviate the need to add clindamycin in patients undergoing cesarean delivery in the presence of intraamniotic infection.

In the past 3 years three studies[40-42] evaluated intrapartum versus postpartum treatment of intraamniotic infection. These three studies consistently demonstrated a lower rate of neonatal sepsis with intrapartum treatment (Table VI).

In 1987 Sperling et al.[40] reported the first systematic study to determine whether maternal intrapartum antibiotic therapy would reduce the incidence of maternal and neonatal complications. In cases collected between 1981 and 1986 they reported a nonrandomized allocation as to timing of treatment (intrapartum versus immediately post partum). All patients were treated with penicillin G (5 million units intravenously every 6 hours) plus gentamicin (1.5 mg/kg every 8 hours). After birth, neonates had blood cultures obtained and chest roentgenography performed within 2 hours of birth, and neonatal treatment with ampicillin plus gentamicin was started for 72 hours in all infants. If neonatal sepsis or pneumonia were diagnosed, the antibiotics were continued for 10 days. During that time interval most patients were treated intrapartum, with postpartum treatment being deferred for those patients who were likely to be delivered within approximately an hour after the diagnosis of intraamniotic infection.

In that study of 257 patients intrapartum therapy was given to 80% ($n = 211$) and postpartum treatment was given to the remainder ($n = 46$). There was no difference in duration of membrane rupture, gestational age, or cesarean section rate, but patients who received intrapartum treatment had a longer mean interval from the diagnosis of intraamniotic infection to delivery (4.7 ± 3 vs 1.8 ± 2.1 hours, $p < 0.001$. Maternal outcome was not different between the two groups, but neonatal sepsis (2.8% vs 19.6%, $p < 0.001$) and neonatal death from sepsis (0.9% vs 4.3%, $p = 0.07$) were decreased in the group receiving intrapartum treatment (Table VI).

Another retrospective study was reported by Gilstrap

Table V. Effect of clinical chorioamnionitis on outcome of preterm infants with premature rupture of membranes[37]

	Chorioamnionitis ($n = 92$)	No chorioamnionitis ($n = 606$)	p Value
Gestational age (wk)	30.2	31.2	
Mortality (%)	25	6	<0.01

Gilstrap et al.[41]	273	1.5	5.7	0.06
Gibbs et al.[42]	45	0	21	0.03

*Positive blood culture.

et al.[41] from Parkland Memorial Hospital in Dallas. One hundred thirty-three cases of chorioamnionitis with intrapartum maternal treatment were compared with 140 cases with no intrapartum treatment (all pregnancies ≥35 weeks). Overall, bacteremia occurred in 1.5% of the intrapartum treatment group versus 5.7% of the group without intrapartum treatment ($p = 0.06$). In particular, group B streptococcal bacteremia occurred in none of the intrapartum treatment group and 5.7% of the group without intrapartum treatment ($p = 0.004$). There were only 39 cases with chorioamnionitis at ≤34 weeks' gestation and no cases of bacteremia were reported. The authors felt that these observations were consistent with the concept that intrapartum treatment decreases neonatal bacteremia.

Because of study design deficiencies of these previous trials and the importance of the clinical question, Gibbs et al.[42] performed a randomized trial of intrapartum versus immediate postpartum treatment in women with intraamniotic infection. By randomization, all mothers received ampicillin (2 gm intravenously every 6 hours) plus gentamicin (1.5 mg/kg every 8 hours). In addition, if cesarean delivery was performed, clindamycin was added post partum. Enrollment in this study was limited to patients with intraamniotic infection at ≥34 weeks' gestation and with cervical dilatation ≥4 cm. We limited enrollment to these patients out of concern for untreated intraamniotic infection with premature infants and for prolonged labor without treatment. (We reasoned that observations in the study group could be applied to the groups specifically excluded.) Vaginal, blood, and amniotic fluid cultures were obtained. After delivery, neonates had blood cultures and a chest x-ray film obtained. A cerebrospinal fluid culture was performed only with referrable signs. Neonatal treatment consisted of ampicillin (75 mg/kg intravenously every 12 hours) plus gentamicin (2.5 mg/kg every 12 hours), begun within 1 to 2 hours after birth. Antibiotics were continued for at least 72 hours. If sepsis or neonatal pneumonia was diagnosed, antibiotics were continued for 10 days. After enrollment of 45 evaluable patients, the study was stopped by joint decision of the investigators and an impartial safety committee.

There were no significant differences between the intrapartum and postpartum treatment groups with regard to any labor parameter or with regard to maternal genital cultures.

Maternal outcome measures consisting of maximum postpartum temperature, postpartum hospital stay, and number of febrile days were all significantly improved in mothers with intrapartum treatment ($p = 0.05$). It is more important, however, that neonatal outcome was improved. With the groups well matched with regard to gestational age and birth weight, early neonatal sepsis occurred in none of the intrapartum treatment group versus 21% of the postpartum treatment group ($p = 0.03$). If we consider sepsis or pneumonia, then these complications occurred in none of the intrapartum treatment group versus 32% of the postpartum treatment group ($p = 0.003$). The decrease in neonatal infections was accompanied by a 2-day shorter hospital stay (3.8 ± 1.1 vs 5.7 ± 3.0, $p = 0.02$). The only late infection (a case of delayed neonatal sepsis) occurred in the postpartum treatment group.

In this study we concluded that intrapartum versus immediate postpartum antibiotic treatment of intraamniotic infection resulted in improved maternal and neonatal outcome.

On the basis of these three studies, the benefits of intrapartum maternal treatment clearly outweigh any theoretic disadvantage such as interference with neonatal cultures.

Route of delivery. As noted, cesarean delivery should be reserved for cases of intraamniotic infection with additional standard obstetric indications for abdominal delivery. The cesarean section rate is increased, however, to approximately 35% to 40% because of its increased likelihood in cases of intraamniotic infection, primarily as a result of dystocia and secondarily fetal distress.[40]

When abdominal delivery is necessary, the standard transperitoneal, low-cervical transverse approach is most commonly used and results in a good outcome. Cesarean hysterectomy should be reserved for patients who have additional obstetric or gynecologic indications for hysterectomy (such as cervical dysplasia or uterine myomas) or supervening obstetric complications (such as refractory uterine atony). Indeed, the likelihood of

uterine atony is increased in patients with intraamniotic infection, as well as in patients who have received high doses of oxytocin during labor. However, in most cases uterine atony may be controlled medically with drugs, including 15-methyl-prostaglandin $F_{2\alpha}$.[43]

In the past several authors[44, 45] have recommended extraperitoneal cesarean section when abdominal delivery was indicated in patients with intraamniotic infection. In the only comparative study, however, Yonekura et al.[46] found no benefit to extraperitoneal cesarean section as compared with transperitoneal cesarean section regarding avoidance of major complications or shortening hospital stay. In addition, in 11.5% of the experitoneal cesarean sections there was inadvertent entry into either the bladder or the peritoneum. Accordingly, extraperitoneal cesarean section, a technique practiced by few obstetricians at any rate, appears to offer no special advantage even in cases of amnionitis.

Long-term outcome

In the last few years, two studies have looked at the influence of clinical chorioamnionitis on long-term prognosis of the infants. In 1985 Hardt et al.[47] compared the outcome of 42 low birth weight infants born from pregnancies complicated by chorioamnionitis to 31 infants of similar weight born after premature rupture of the membranes but without chorioamnionitis. Infants born after chorioamnionitis occurred had significantly lower mental development index scores (104 ± 18 vs 112 ± 14, $p = 0.017$) and lower physical development index scores (92 ± 21 vs 101 ± 21, $p = 0.098$). Two years later, Morales[87] reported these scores in preterm infants born of pregnancies complicated by chorioamnionitis and from control infants born after premature rupture of the membranes but without chorioamnionitis. The mental development and physical development scores were not significantly different. However, cases of chorioamnionitis were matched with controls on the basis of severity of respiratory distress syndrome and intraventricular hemorrhage. Since both respiratory distress syndrome and intraventricular hemorrhage were significantly increased in cases of chorioamnionitis, it appears to us to be inappropriate to match on the basis of these complications. Thus it may be concluded that clinical chorioamnionitis per se may not adversely affect mental and physical development; however, because chorioamnionitis is accompanied by increases in complications such as respiratory distress syndrome and intraventricular hemorrhage, clinical chorioamnionitis may indirectly lead to lower development scores.

Synergistic effect of intraperitoneally administered calcium channel blockade and recombinant tissue plasminogen activator to prevent adhesion formation in an animal model

Randall C. Dunn, MD,[a] Alex J. Steinleitner, MD,[b] and Hovey Lambert, PhD[b]
Houston, Texas, and Miami Beach, Florida

Previous reports have shown the benefits of calcium channel blockers and recombinant tissue plasminogen activator to prevent postoperative adhesion formation in animal models. To assess the potential benefit of synergistic therapy for the prevention of postoperative adhesion formation, these agents were studied in a rabbit uterine horn model. Four groups of New Zealand White rabbits (n = 8 per group) had a bilateral devascularization injury to the uterine horns. Before closure saline solution, verapamil hydrochloride (2.5 μ/kg/hour), recombinant tissue plasminogen activator (4 mg total dose), or a combination of verapamil and recombinant tissue plasminogen activator at the stated doses were instilled by means of an Alzet osmotic pump × 200 hours. Adhesion scores were evaluated after this time period by estimating the total uterine horn surface involved in adhesions at a terminal laparotomy and by clinically grading the response to determine whether minimal adhesions formed. Results of the total uterine horn surface scores were (mean score ± SE): saline solution, 44% ± 3.7%; verapamil, 19% ± 4.8%; recombinant tissue plasminogen activator, 11% ± 3.6%; combined, 3% ± 1% ($p < 0.01$ to control and $p < 0.05$ to single-drug therapy). Results of the number of animals per group with minimal adhesions were as follows: saline solution, 0; verapamil, 1; recombinant tissue plasminogen activator, 3; combined, 8 ($p < 0.01$). These results show a synergistic benefit of verapamil and recombinant tissue plasminogen activator to prevent postsurgical adhesion formation when delivered via the intraperitoneal route. (Am J Obstet Gynecol 1991;164:1327-30.)

Key words: Calcium channel blocker, recombinant tissue plasminogen activator, adhesions

The development of postoperative adhesions is a significant concern to general and gynecologic surgeons. Their role as a cause of clinical morbidity such as small bowel obstruction or infertility is well recognized. As the pathogenesis of postoperative adhesion formation has become better elucidated, numerous agents have been tested for their ability to reduce the incidence of adhesion formation in the postoperative setting.[1-3] Combinations of different agents to specifically influence certain aspects of the adhesion formation cascade have been attempted with little success.[4-7]

Investigations have shown the individual benefit of calcium channel blockers and recombinant tissue-type plasminogen activator on postoperative adhesion formation.[8-10] Calcium is known to play an important role in the regulation of numerous elements of the inflammatory process and regenerative process.[11] Depressed fibrinolysis predisposes injured peritoneal surfaces to produce early fibrinous adhesions that eventually become collagenous adhesions after the ingrowth of fibroblasts. Decreased plasminogen activator as a result of surgically induced ischemia has been postulated as a unifying pathogenetic mechanism of this process.[12-14]

Because treatment with calcium channel blockade and treatment with recombinant tissue plasminogen activator has each been shown to enhance postsurgical peritoneal repair with less adhesion formation in animal models, this study was undertaken to determine whether the synergistic effects of these two types of agents would enhance their ability to decrease postoperative adhesions compared with the effect of either agent alone.

Material and methods

Twenty-four New Zealand White rabbits weighing 2.75 to 3.25 kg were used as a model for postoperative adhesion formation. Animals were randomly assigned to one of four groups (n = 8 in each group): saline solution control, verapamil hydrochloride (Knoll Pharmaceutical Company, Whippany, N.J.) treatment, recombinant tissue plasminogen activator (Genentech,

Inc., South San Francisco, Calif.) treatment, and both verapamil hydrochloride and recombinant tissue plasminogen activator treatment. Animals were housed and maintained preoperatively, intraoperatively, and postoperatively in accordance with the regulations of the Baylor Small Animal Program.

A low-midline laparotomy was performed under aseptic conditions. A rabbit uterine horn devascularization model was used as an ischemic stimulus for adhesion formation. The uterine horns were devascularized by bipolar cauterization (power setting 40, duration less than 1 second; Malis CMC-1 bipolar electrocautery apparatus, Codman Shurtless Inc., Randolph, Me.) of the uterine mesenteric vascular arcade and its anastomotic branches below the horns so that approximately 3 cm of each horn was rendered ischemic, as documented by uterine horn blanching before closure. Drug delivery was by means of Alzet miniosmotic pumps (model 2001 and 2ML, Alza Corp., Palo Alto, Calif.) sutured on the upper anterior abdominal wall before closure. Drugs and saline solution were reconstituted and installed into the miniosmotic pumps immediately before placement in each animal. In all cases the surgeon was blinded as to which pumps contained experimental drugs or saline solution. The abdominal incisions were closed in two layers with 2-0 and 4-0 polyglycolic acid sutures. Animals were killed on postoperative day 8 and adhesions were scored. Adhesion scores were on the basis of the total uterine horn percentage involvement in adhesions. Adhesion scores were performed in a blinded fashion as to the treatment status of the animal. In addition, adhesions were scored in a clinical fashion: animals with ≤5% of the total uterine horn surface were defined as having minimal adhesions. No additional postoperative adhesion prevention adjuncts were used and no perioperative antibiotics were used.

The drug dosages used were 2.4 μg/kg per hour for verapamil hydrochloride and 4 mg total dose for recombinant tissue plasminogen activator. Delivery rates of the two different miniosmotic pump models achieved total delivery by 200 hours. Dosages were used so that essentially complete delivery of the drugs was accomplished by the end of the study. Doses were used that had previously been effective in the reduction of postoperative adhesions in this or similar models at a level where there was also an opportunity to show synergism.

Statistical analysis was performed by analysis of variance by ranks (Kruskal-Wallis test) among groups. Results are presented as mean ± SE; χ^2 analysis was used to assess the differences in animals with minimal adhesions among groups. Statistical significance was defined as $p < 0.05$.

Results

All 32 animals tolerated the procedure well and were able to be evaluated at the terminal laparotomy. There were no bleeding, infectious, or wound-healing complications clinically observed postoperatively. The uterine horn injury produced adhesions in all control-treated animals, consistent with previous studies with this model. There was no clinical evidence of intraabdominal abscess formation or gangrenous change of any uterine horn at the terminal laparotomy. Adhesions, when they occurred, were primarily between the uterine horns themselves, but also occasionally to the adjacent bowel or bladder.

Results of the adhesion scores are presented in Table I and summarized as follows: saline solution, 44% ± 3.7%; verapamil, 19% ± 4.8%; recombinant tissue plasminogen activator, 11% ± 3.6%; combined verapamil and recombinant tissue plasminogen activator, 3% ± 1% ($p < 0.01$). A significant difference in postoperative adhesion formation was also seen between the two individual drugs' effectiveness and the synergistic effectiveness of the two drugs, $p < 0.05$ (also Table I). Animals with clinically defined minimal adhesions also were statistically different among the groups as presented in Table II. All eight animals in the combined drug group had minimal adhesions, whereas no animals in the saline solution group, one animal in the verapamil group, and three animals in the recombinant tissue plasminogen activator group had minimal adhesions. Without the statistical effect of the combined

drug group, there was no significant difference among the other three groups in the production of minimal adhesions.

Comment

Inasmuch as the mechanisms of postoperative adhesion formation have become understood, multiple modalities to prevent adhesions have been tried, either alone or in combination. The two recent therapeutic modalities presented here, which alone have been shown to enhance normal peritoneal healing, calcium channel blockade by verapamil hydrochloride and increased postoperative fibrinolysis by the addition of recombinant tissue plasminogen activator, have in this study shown increased effectiveness when used synergistically in this animal model.

The mechanism(s) by which calcium channel blockade influences the events of adhesion formation are not certain. Experimental evidence exists for several potential effects on the adhesion formation cascade. Calcium blocking agents are known to modulate the extent of tissue damage after ischemic cellular injury.[15, 16] Calcium channel blockade may also affect other humoral or cellular aspects of the acute inflammatory response. Evidence of its influence on parameters including reduced histamine release, altered prostaglandin release, and platelet aggregation may reduce the inflammatory response to tissue injury.[17-19] Calcium channel blockers' activity have shown a decreased fibrin-rich exudate after the inflammatory response because of fewer microscopic pores in small vessels.[20] After the injury, penetration of fibrin-rich matrices by fibroblasts is inhibited by these agents.[21]

The mechanism by which effects of recombinant tissue plasminogen activator reduced postoperative adhesion formation is a result of enhanced fibrinolytic activity. The importance of the fibrinolytic system in the pathogenesis of adhesions was postulated more than 15 years ago.[12-14] The fibrinolytic system is responsible for clearing the fibrin-rich exudate that is formed after surgical injuries. Plasminogen, the inactive proenzyme, is converted to plasmin by tissue-type plasminogen activator and other plasminogen activators.[22, 23] Tissue-type plasminogen activator's activity is enhanced several hundredfold in the presence of fibrin becaue of lysine binding sites on the fibrin surface; this confines plasmin's main proteolytic activity to the appropriate site. After plasmin has caused fibrin degradation, which results in fibrin-split products, plasmin is released and rapidly inactivated by plasmin inhibitors.[24, 25]

Possible points of synergistic activity in the reduction of postoperative adhesions shown by verapamil and recombinant tissue plasminogen activator were not directly studied in these experiments. From the mechanisms of action of the two drugs already mentioned, a possible mechanism might be explained by a decreased inflammatory response after the initial ischemic injury, leading to a decreased fibrin-rich exudate being released at the surgical site, which in turn is lysed by the enhancing fibrinolytic activity of recombinant tissue plasminogen activator. Multiple factors such as timing of drug intervention and total dose of drug used may further affect the outcome.

In conclusion, a significant synergistic effect on prevention of postsurgical adhesion formation was seen with the use of a calcium channel blocker, verapamil, and recombinant tissue-type plasminogen activator at the stated doses, as compared with either drug alone. Synergistic effects are probably a result of the mechanism of action of these two different drugs and their effects on the postoperative adhesion-formation cascade.

Endothelin and neuropeptide Y are vasoconstrictors in human uterine blood vessels

Gabriel Fried, MD, PhD,[a, b] and Ulf Samuelson, MD, PhD[a, c]
Stockholm, Sweden

The control of uterine blood flow is regulated by a number of factors including vasoactive substances present in the endothelium and the perivascular nerves. We examined the effects of two vasoactive peptides, endothelin and neuropeptide Y, on segments of human uterine arteries and veins in vitro. We found endothelin, a potent vasoconstrictor in the uterine artery and vein, giving a slow and long-lasting contraction starting at 10^{-9} mol/L. At this concentration, the established vasoconstrictor noradrenaline had almost no effect. Neuropeptide Y had no effect of its own in the human uterine artery, but increased basal tone in uterine veins, and at higher concentrations triggered spontaneous contractions. Neuropeptide Y (10^{-7} mol/L) often, but not always, enhanced the contraction induced by noradrenaline (10^{-6} mol/L). Neuropeptide Y (10^{-7} mol/L) also enhanced the contraction induced by transmural nerve stimulation (20 Hz, 0.4 msec). We conclude that endothelin and neuropeptide Y may modulate the control of human uterine circulation. (Am J Obstet Gynecol 1991;164:1330-6.)

Key words: Endothelin, neuropeptide Y, noradrenaline, neuropeptides, uterine artery

Endothelin is a recently discovered 21–amino acid polypeptide with very strong vasoconstrictor effects that occurs in and is released from vascular endothelial cells.[1, 2] Because of its localization and potency, the peptide has been suggested to be involved in vasospastic disorders and hypertension.[1, 3]

Neuropeptide Y is a 36–amino acid polypeptide originally isolated from porcine brain.[4] With the use of immunohistochemical techniques, neuropeptide Y was found in most peripheral tissues of several species including man. Neuropeptide Y–like immunoreactivity is found together with markers for noradrenaline in a population of peripheral sympathetic neurons, with a particularly rich supply to blood vessels.[5] It is known that noradrenaline causes a concentration-dependent contraction of the uterine artery, mediated primarily by α_1-adrenoreceptors.[6, 7]

In the female reproductive tract noradrenaline and neuropeptide Y nerves have been found around ovarian and uterine vessels as well as in the oviduct and the

myometrium.[8, 9] The myometrial noradrenaline nerves are known to degenerate during pregnancy[10] and it was also found that the coexisting neuropeptide Y disappeared.[8, 11] However, in patients with preeclampsia the myometrial levels of noradrenaline and neuropeptide Y were significantly higher than those in normal pregnant women.[11] The role of endothelin in uterine vessels is unknown. To evaluate the possible significance of noradrenaline and neuropeptide Y nerves and endothelin in the human female reproductive tract, we have examined the effects of neuropeptide Y and endothelin on human uterine vessels in vitro.

Methods

Human uterine and ovarian arteries and veins were obtained from 15 patients aged 46 ± 7 years (mean ± SD, range 37 to 59) undergoing hysterectomy because of myoma or bleeding disorders. No patients with malignant disease or patients receiving radiologic cytotoxic, or antihypertensive therapy were included (see Table I). A total of 36 vessel segments were used. The vessels were excised before, or at most within 10 minutes of, clamping the blood flow, and immediately put in ice-cold Ringer solution. The vessels (outer diameter 2 to 3 mm) were dissected free from connective tissue under a stereo microscope and 2 to 3 mm long circular segments of the vessels were mounted vertically in 5 ml organ baths containing Krebs-Ringer solution (37° C) of the following composition (in millimoles per liter): sodium chloride 120.3, potassium chloride 5.9, calcium chloride 2.5, magnesium chloride 1.2, sodium bicarbonate 15.5, sodium biphosphate 1.2, glucose 11.5. The baths were bubbled with a gas mixture of 94% oxygen and 6% carbon dioxide to keep the pH in the bath at 7.35 to 7.45. Care was taken not to damage the endothelium unintentionally. In some preparations the endothelium was removed by gently rubbing with a forceps. The presence and absence of the endothelium was confirmed by addition of acetylcholine (10^{-7} mol/L) or substance P (10^{-8} mol/L) to preconstricted vessels. In vessels with intact endothelium the substances produced a pronounced relaxation. The vascular tension was recorded isometrically with a Grass FT03C force-displacement transducer and registered on a Grass model 7 polygraph. The organ baths were equipped with two platinum electrodes (10 mm long, 10 mm apart); a Grass S44 stimulator was used for electrical stimulation. The vessels were given an initial passive load of 10 to 15 mN and allowed to equilibrate for at least 60 minutes before the experiments.

Drugs were dissolved in 0.9% sodium chloride and added to the baths in volumes of 5 to 50 μl. New additions after wash were performed when a stable baseline was obtained (after at least 10 minutes). When two drugs were added to the same preparation, the interval was usually 5 minutes. The response to the added substances was expressed in percentage ± SEM of the maximal contraction elicited by noradrenaline (10^{-5} mol/L) (E_{max}) for each vessel to minimize variations in absolute contractile response. Dose-response curves were constructed from steady states. Also, pD_2 (the negative logarithm of the agonist concentration inducing 50% of the E_{max}) was computed. The neuropeptide Y initially used was a gift from Dr. K. Tatemoto, but was later obtained from Cambridge Research Biochemicals (Cambridge, United Kingdom); endothelin was obtained from Peninsula Laboratories Europe Inc. (Merseyside, United Kingdom); acetylcholine and substance P were from Sigma Chemical Co., St. Louis).

Statistical analysis was performed with the Mann-Whitney test, and $p < 0.05$ was considered significant.

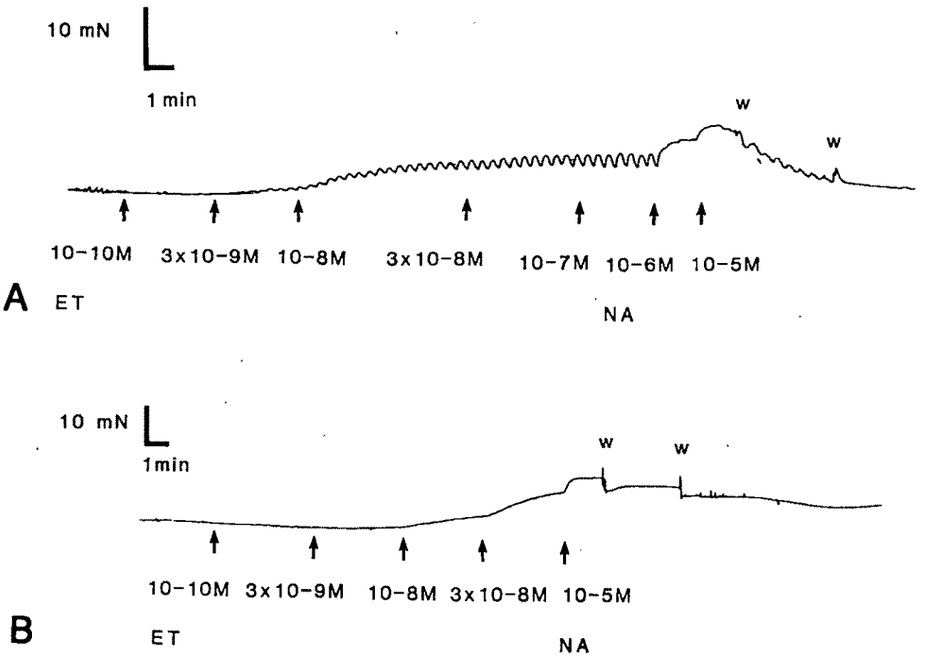

Fig. 1. A, Effect of endothelin (10^{-10} to 10^{-7} mol/L) on human uterine artery. Note slowly developing, long-lasting contraction and gradually developing rhythmic activity. After addition of noradrenaline (10^{-6} to 10^{-5} mol/L) the vessel rapidly contracted further. *w*, Wash. **B,** Effect of endothelin (10^{-10} to 3×10^{-8} mol/L) on human uterine vein. After addition of noradrenaline (10^{-5} mol/L) the vessel contracted further. *w*, Wash.

Table II. Values ± SEM for pD_2 and E_{max} from concentration-response curves to noradrenaline and endothelin

Agonist	pD_2	E_{max}
Noradrenaline	5.9 ± 0.2	95.7 ± 9.0
Endothelin	7.8 ± 0.2	77.0 ± 7.0

pD_2 Value is the negative logarithm of the agonist concentration, causing 50% of the E_{max} response. E_{max} is expressed as the percentage of the maximal stimulation with noradrenaline in the beginning of the experiment.[7]

Results

Noradrenaline at 10^{-8} to 10^{-5} mol/L caused dose-dependent contractions of uterine arteries. The maximal dose caused contractions of 12.0 ± 1.4 mN (n = 39, mean ± SEM). Uterine veins also contracted with noradrenaline, but the contractile force was lower than that in the arteries, 5.4 ± 1.2 mN (n = 9). Phentolamine (10^{-5} mol/L) abolished the contractile response evoked by noradrenaline.

Endothelin induced concentration-dependent contractions of the uterine arteries, starting at 3×10^{-9} mol/L. At 10^{-8} mol/L the contraction was 35.8 ± 7.9% (n = 10), and at 3×10^{-8} mol/L, the contraction was 64.5% ± 13.9% (n = 11) of the maximal noradrenaline contraction. The contraction developed slowly and was always accompanied by a rhythmic activity centered around the increase in tone (Fig. 1, *A*). When NA (3×10^{-6} mol/L) was added during the maximal endothelin-induced contraction, the vessels rapidly contracted further by approximately 30% (Fig. 1, *A*). The vessels relaxed slowly after wash. Uterine veins also responded to endothelin, starting at 10^{-9} mol/L. At 3×10^{-8} mol/L the contraction was 50.0 ± 19.0% of the maximal noradrenaline contraction (n = 4) (Fig. 1, *B*). The concentration-response curves, E_{max} and pD_2 for noradrenaline and endothelin are seen in Fig. 2 and Table II, and show that endothelin is severalfold more potent than noradrenaline on an equimolar basis.

The neuropeptide Y given at doses from 10^{-10} to 10^{-7} mol/L increased basal tone of uterine veins, and at 10^{-7} mol/L often triggered a spontaneous contractile activity (Fig. 3, *B*). The contraction was 36.1 ± 2.6% (n = 7) of the maximal noradrenaline contraction. In uterine arteries there were no clearcut effects on tone or contractility by neuropeptide Y (10^{-10} to 10^{-7} mol/L) given alone.

In uterine arteries, the contraction evoked by noradrenaline (10^{-6} mol/L) was usually enhanced by ad-

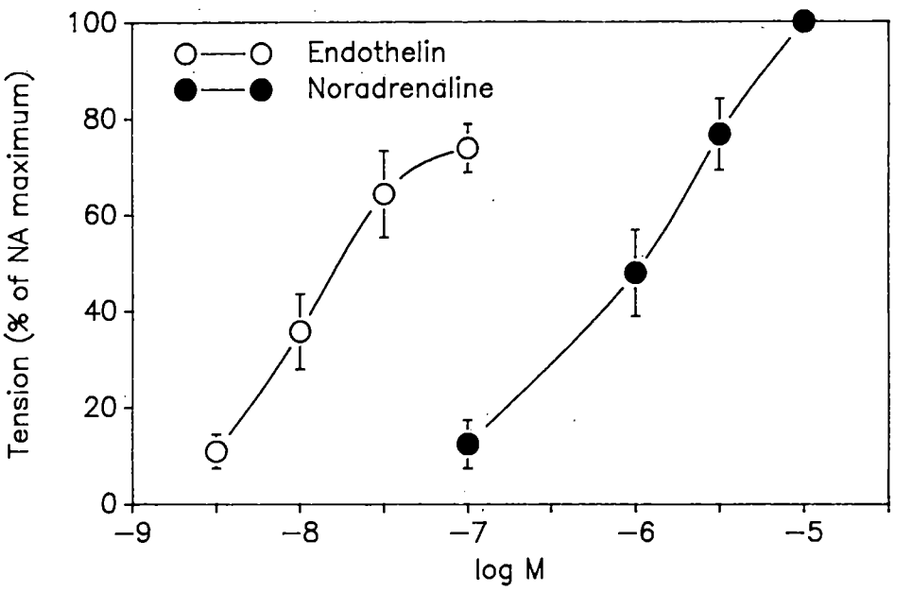

Fig. 2. Concentration-response curve of endothelin and noradrenaline in human uterine artery. On the X-axis, concentration of endothelin or noradrenaline (10^{-9} to 10^{-5} mol/L); on the Y-axis, tension in percentage of maximum tension obtained by noradrenaline (10^{-5}). Each point is the average of three measurements ± SEM.

dition of neuropeptide Y (10^{-7} mol/L) before addition of noradrenaline. The contraction by noradrenaline (10^{-6} mol/L) was 48.0 ± 9.1%, whereas noradrenaline (10^{-6} mol/L) followed by neuropeptide Y (10^{-7} mol/L) increased the contractile response to 76.9 ± 7.4% ($p < 0.05, n = 14$). The increase in the contractile response in this series was at most 60% (Fig. 3, *A*). However, this response was variable, in four vessels an inhibition was seen. The effects of neuropeptide Y appeared to be independent of the endothelium because no difference in reactivity was seen whether the endothelium was rubbed or not. There was no relation between effect of neuropeptide Y and cycle phase or age of the patients. In uterine veins noradrenaline produced a weaker contractile response that was not changed by addition of neuropeptide Y.

In arteries the contractile response evoked by transmural nerve stimulation (20 Hz, 0.4 milliseconds, 60 V, 10-second stimulation with 3-second interval) was slightly potentiated by neuropeptide Y (10^{-7} mol/L) (23.8 ± 4.8% before neuropeptide Y, 40.8 ± 4.2% after neuropeptide Y (10^{-7} mol/L; $p < 0.05$; $n = 5$). The contractile response to field stimulation was not completely blocked by tetrodotoxin (0.1 μg/ml). In uterine veins neuropeptide Y caused an increased basal tone but the amplitude of the stimulation-induced peak was unchanged.

Isolated observations on ovarian vessels gave effects of neuropeptide Y similar to those on uterine vessels. On ovarian veins, neuropeptide Y (10^{-7} mol/L) caused increased basal tone up to 30% to 40% of the maximal and also triggered spontaneous contractions as in uterine veins ($n = 2$). On ovarian artery, neuropeptide Y increased basal tone slightly but did not trigger contractions ($n = 1$).

Comment

These findings show that endothelin is a very potent vasopressor agent in human uterine arteries and veins, and that it is considerably stronger than noradrenaline on an equimolar basis at concentrations below 10^{-7} mol/L. The potent vasoconstrictor effects of endothelin have previously been shown in several vascular beds including the coronary, renal, and skeletal circulation of human beings and the rat.[12-15] In addition, endothelin causes contractions of rat myometrial smooth muscle.[16] The threshold level for activation found in human coronary arteries (10^{-8} mol/L)[13] was similar to that found in the uterine vessels in this study. The potent and long-lasting effects of endothelin can be reversed by dihydropyridine Ca^{++}–channel blockers such as nifedipine and nicardipine,[1, 13, 17] which has led to the suggestion that endothelin may be an endogenous agonist of such Ca^{++} channels.[1, 17] The potent vasoconstriction of the uterine artery elicited by low concentrations of endothelin seen in this study together with

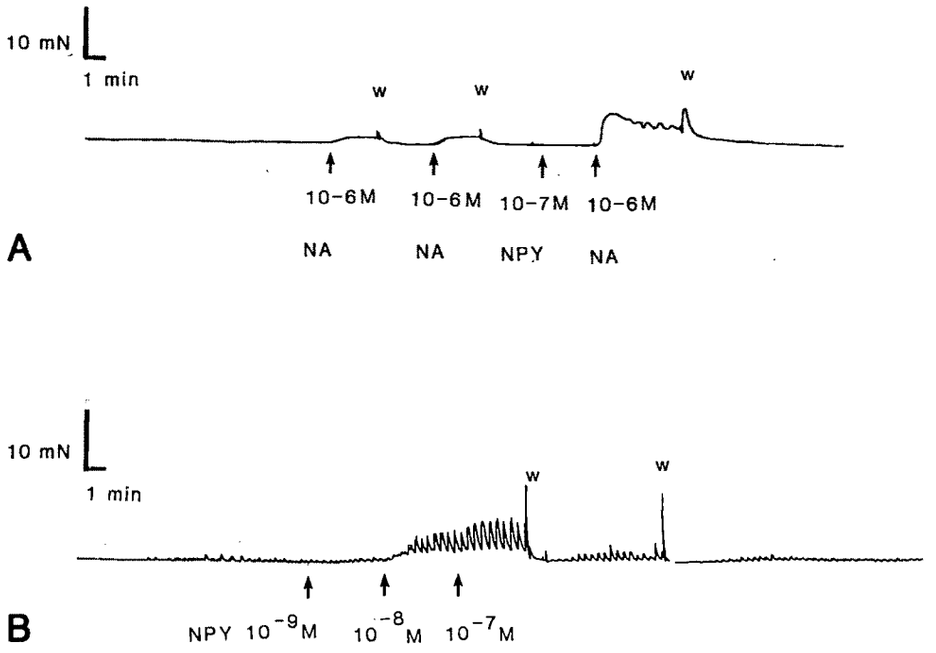

Fig. 3. A, Effects of neuropeptide Y and noradrenaline on human uterine artery in vitro. Neuropeptide Y (10^{-7} mol/L) has no effect by itself, but enhances the contraction caused by noradrenaline (10^{-6} mol/L). *w*, Wash. **B,** Effects of neuropeptide Y on human uterine vein in vitro. Neuropeptide Y causes an increase in tone at 10^{-9} mol/L and triggers spontaneous contractions at 10^{-8} mol/L, which increases amplitude at 10^{-7} mol/L. The effect is reversible and disappears after wash *(w)*.

observations that endothelin is present in vascular endothelial cells indicate that this substance may be involved in vasospastic disorders related to the uterine circulation. However, further investigation of the presence in and release of endothelin from uterine vessels in physiological and pathophysiological states is needed.

The present results also demonstrate that although neuropeptide Y has been reported to be a potent vasopressor in vivo, the effects of neuropeptide Y alone on human uterine vessels in vitro are relatively modest. We found no direct effect on arteries and a moderate vasoconstrictor effect on veins. The ability of neuropeptide Y per se to cause vasoconstriction has previously been demonstrated in various vessels, and the response varied both with vessel type and species. Vessels that have been reported to exhibit a strong sensitivity to neuropeptide Y per se are cerebral arteries and iliac and femoral veins from rabbit and guinea pig.[18-20] It is interesting that small intracervical branches of the human uterine artery appear to be directly sensitive to neuropeptide Y,[21] indicating that there might be regional differences in the reactivity to neuropeptide Y in the uterine vasculature, possibly related to vessel size.[14] Direct effects of neuropeptide Y on the uterine artery have also been seen in the guinea pig, where neuropeptide Y causes long-lasting contractions of isolated arterial segments.[22] Low concentrations of neuropeptide Y (10^{-8} to 3×10^{-7} mol/L) were more potent than equimolar concentrations of noradrenaline, something that has been observed also in vivo on the pregnant guinea pig artery.[23] Other workers have reported only a weak direct effect of neuropeptide Y in the guinea pig uterine artery.[24]

Although we did not see any direct effect of neuropeptide Y on tone or contractility of the uterine artery or ovarian artery, there was a clear effect on uterine and ovarian veins, with increased tone and a triggering of spontaneous contractions. This effect has also been noted in femoral veins.[20]

The potentiating effect of neuropeptide Y (10^{-7} mol/L) on noradrenaline–induced (10^{-6} mol/L) contractions seen in this study has previously been reported both in uterine artery and in other types of arteries.[19, 24, 25] However, not all preparations show potentiation, and the inconsistent response has been examined by Hanko et al.[26] in a large series of experiments on several types of vessels. The reason(s) for this variability is not clear, but does not seem to be related to hormonal status, age of the patients, or endothelial fac-

tors. It may be because of other factors related to the heterogeneous patient material and variations in sample handling. It might also involve interactions with endogenous compounds on the second-messenger level. Support for this view is the observation that neuropeptide Y also potentiates the response to other substances, such as histamine.[19] It was previously determined that interactions between many vasoactive agents, such as noradrenaline and 5-hydroxytryptamine, often cause an enhanced contractile response,[27] indicating that interactions of this kind are not primarily restricted to first-messenger mechanisms.

Transmural nerve stimulation–induced contractions were potentiated by neuropeptide Y in this study, in agreement with several other studies on various vessels in human beings and experimental animals (femoral artery and vein, superior mesenteric artery, portal vein, basilar artery, gastroepiploic artery).[14, 26] Neuropeptide Y also causes a depression of transmural nerve stimulation–evoked tritium-noradrenaline efflux in these vessels and in other organs, such as the fallopian tube and vas deferens.[9, 28] The mechanisms by which neuropeptide Y causes a postsynaptic potentiation of the contractile response in parallell with a presynaptic depression of noradrenaline outflow are not clear but have been discussed in terms of neuropeptide Y–induced changes in muscle tone and concomitantly an increased sensitivity to other vasoactive agents.[14, 26]

The postjunctional contractile adrenergic receptors in the human uterine artery have been pharmacologically characterized in detail as to be primarily of the α_1-type,[6] although α_2-receptors have also been reported.[7] Neither the effects of endothelin or neuropeptide Y are sensitive to α-adrenoreceptor blocking agents, and these two substances appear to mediate their effects through receptors of their own.[16, 20]

In conclusion, this study has shown effects of neuropeptide Y on nonpregnant human uterine artery, indicating that neuropeptide Y modulates vasoconstriction induced by noradrenaline or transmural nerve stimulation. The effects of endothelin on the human uterine artery showed that endothelin induces a slowly developing and long-lasting vasoconstriction. It is suggested that endothelin and neuropeptide Y may modulate the control of human uterine circulation and may be involved in regional vasospastic disorders.

Behavioral changes in fetal sheep caused by vibroacoustic stimulation: The effects of cochlear ablation

Michael J. Parkes, DPhil,[a] Peter J. Moore, PhD,[a] David R. Moore, PhD,[b] Nicholas M. Fisk, MB, BS,[a] and Mark A. Hanson, DPhil[a]

Reading, England

We measured the effects of 2 minutes of vibroacoustic stimulation on the activity of unanesthetized fetal sheep in utero. We were unable to detect any changes in activity after stimulation with a model 5C electrolarynx. With more powerful stimulation using a mechanical oscillator, fetal electrocortical activity desynchronized. Fetal breathing and eye movements changed with electrocortical activity and there was an increase in nuchal muscle activity. Stimulation caused a small decrease in fetal heart rate. Responses to stimulation were not seen in four of the five fetuses with bilateral cochlear ablation. These results indicate that in fetal sheep the auditory apparatus is necessary for the detection of vibroacoustic stimuli. The difference in responsiveness of the sheep and human fetus appears to be because of a difference in central processing after detection of the stimulus. (Am J Obstet Gynecol 1991;164:1336-43.)

Key words: Fetal sheep, vibroacoustic stimulation, electrocortical activity, heart rate, cochlear ablation

The human fetus in the late phase of gestation is responsive to externally applied vibroacoustic stimulation. A 5-second stimulus with an electrolarynx held against the maternal abdomen causes large and sustained alterations in fetal visceral and somatic motor activity.[1, 2] These include increased heart rate, body movements, and eye blinking[3] and decreased fetal breathing movements. Because little is known about the central nervous system mechanisms that detect and process vibroacoustic stimuli, we wished to investigate the effects of external vibroacoustic stimulation on chronically instrumented and unanesthetized fetal sheep.

Previous studies have shown that in fetal sheep auditory and somatosensory pathways appear to be functional.[4, 5] Measurements of the passage of externally applied vibroacoustic stimuli into the amniotic cavity indicate that the attenuation can be relatively small, especially of frequencies below 5 kHz, and is similar in

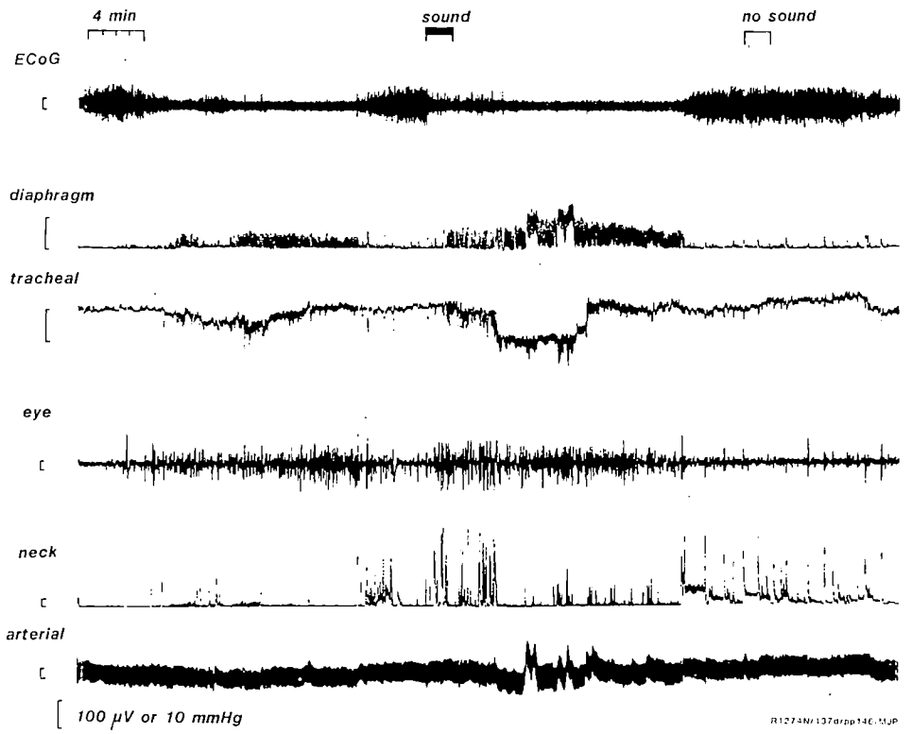

Fig. 1. The effects of stimulation in high voltage electrocortical activity on electrocortical state, diaphragm, eye and nuchal electromyograms, tracheal and arterial minus amniotic pressures in one fetus at 137 days' gestation. *ECoG,* Electrocortical activity. *min,* Minutes.

sheep and man.[6] Fetal sheep also appear to detect external vibroacoustic stimulation, inasmuch as stimulation for up to 45 minutes with a model 5C electrolarynx can alter carbon 14 deoxyglucose uptake in the central nervous system.[7] The behavioral responses of fetal sheep to vibroacoustic stimuli are less clear. Preliminary studies with a number of different stimuli[7-11] indicate that fetal sheep may respond, but stimulation with an electrolarynx[7] was found to produce no significant effect on fetal electrocortical state or any obvious increase in fetal body activity.

Therefore we performed controlled trials in fetal sheep to measure any changes in heart rate and somatic motor and electrocortical activity caused by vibroacoustic stimulation. To measure whether the peripheral auditory apparatus is involved in the detection of external vibroacoustic stimuli, we measured the extent to which these changes were present in fetuses with bilateral cochlear ablation.

Methods

Chronically instrumented fetal sheep were prepared as described previously[12] with standard procedures approved by the host institution and in accordance with United Kingdom legislation. Briefly, 12 cross-bred ewes were anesthetized with halothane (1.5% to 2% in oxygen) at 117 to 124 days' gestation. Electrodes were implanted in the fetus to measure diaphragm and nuchal muscle electromyograms and electroocular and electrocortical activity. Catheters for measurement of pressure were placed in a fetal carotid artery, the trachea, and the amniotic cavity. Catheters and electrodes were brought out through the right flank. In five fetuses cochlear ablation was performed bilaterally with an operating microscope by rupture of the round window, aspiration of the cochlear duct via a 16-gauge needle through the round window, and destruction of the modiolus with round cutting burs. At least 5 days were allowed for postoperative recovery, during which time antibiotics were administered to ewe and fetus. Experiments were performed between 129 to 141 days' gestation when fetuses showed normal episodic breathing and electrocortical patterns and had normal pH and blood gas values (mean pH 7.32, SE 0.01; Po_2 22, SE 0.8 mm Hg; Po_2 45, SE 1 mm Hg). Polygraph records were made at a speed of 5 mm per minute and blood pressure readings were taken at 2 mm per second. Electromyogram signals were filtered at 30 Hz and passed through a leaky integrator.

Source of stimulation. In early trials the stimulus used was 5 to 30 seconds from an electrolarynx (model 5C, Western Electric, New York, New York; measured

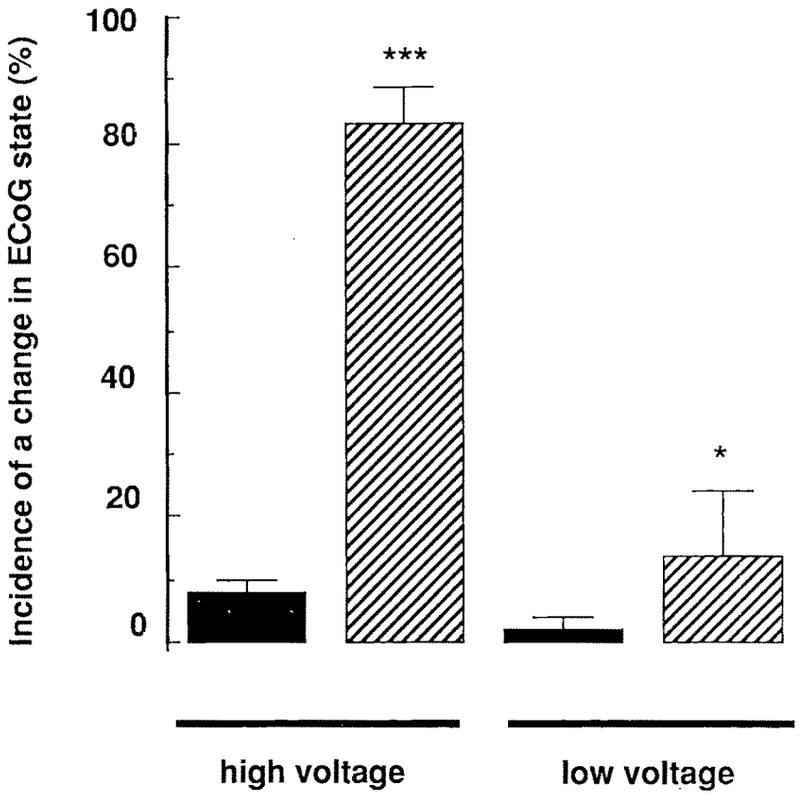

Fig. 2. Mean (±SE) percentage incidence of change in electrocortical state during trials with stimulation *(crossed bars)* or no stimulation *(filled bars)* for trials beginning in high voltage electrocortical state (five fetuses) or low voltage electrocortical state (five fetuses) (n = 252 trials; *one asterisk*, $p < 0.05$; *three asterisks*, $p < 0.001$ for stimulation vs no stimulation in high voltage electrocortical or low voltage electrocortical states). *ECoG*, Electrocortical.

power consumption 0.36 W, disc diameter 3 cm). When this proved ineffective, a function generator was used to provide a square-wave output, the fundamental frequency of which was continuously varied manually between 0.4 and 10 kHz. This stimulus lasted 2 minutes and was applied in every trial. After amplification it was fed into a mechanical oscillator (vibrator 101, Ling Dynamic Systems, Royston, Herts, England) with a measured power consumption from 2 W at 40 Hz to 20 W at 10 kHz. The piston of the oscillator was connected to a plastic disc (diameter 5 cm) covered with ultrasound jelly (Aquasonic 100, Parker Laboratories Inc., Orange, N.J.). Because after surgery the fetal head could not be located with certainty and because the catheters held the fetus to their point of exit (the right side), the piston was applied in every experiment against the right side of the maternal abdomen, approximately 10 cm lateral to the midline. Before experimental trials began, each ewe was accustomed to transducer placement and to the stimulus.

Experimental protocol. Fetal electrocortical state was scored as high voltage or low voltage. When the high voltage electrocortical state was identified, the pretrial period began with the oscillator held against the abdomen of the ewe. After 2 minutes and if still in high voltage, a random number generator determined whether the 2-minute trial was of stimulation or no stimulation. The oscillator was then removed until the next high voltage electrocortical state was identified. The same protocol was followed in the low voltage electrocortical state.

Analysis. During the 2-minute pretrial and trial periods, fetal heart rate (FHR) was counted from the arterial pulse in 10-second intervals; measurements of electrocortical amplitude were made at 36-, 72-, and 108-second points into these periods and also in spontaneous low voltage. During trials the incidence of a change in electrocortical state, the presence of fetal breathing movements, eye movements, and nuchal activity, and the latency (time interval between stimulus onset and first detectable change in electrocortical state) and duration of desynchronizations were measured. On any one day trials were performed in only one electrocortical state, with an average of three trials

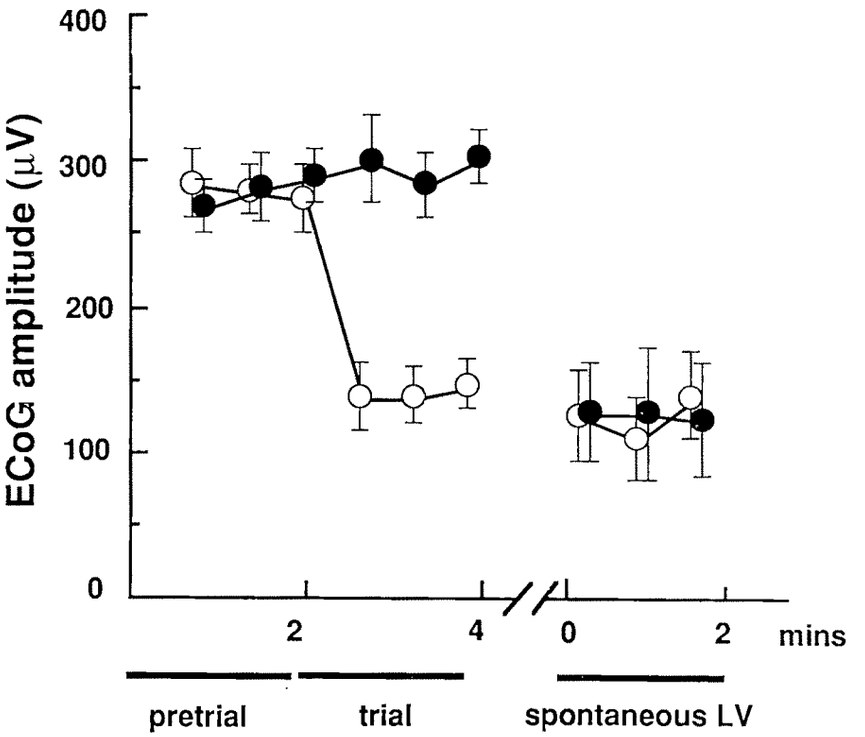

Fig. 3. Mean (± SE) electrocortical amplitude in the 2-minute pretrial and trial periods for stimulation trials begun in high voltage electrocortical state when desynchronization occurred *(open circles)*, no stimulation trials begun in high voltage electrocortical state *(filled circles)*, and in random 2-minute periods of spontaneous low voltage electrocortical state preceding each trial (n = 119 trials in four fetuses). The mean amplitude in the stimulation trial period (131 SE = 5 μV) is significantly lower (*three asterisks*, $p < 0.001$) than that in both pretrial periods (268 SE = 5 μV) and is significantly higher (*one asterisk*, $p < 0.05$) than that in spontaneous low voltage electrocortical state (111 SE = 5 μV). *ECoG*, Electrocortical; *mins*, minutes.

every 2 hours and a maximum of 19 trials. Statistical analysis was performed with standard techniques of nonorthogonal analysis of variance and logistic regression.[13, 14]

Histology. At the conclusion of experiments, animals were killed with pentobarbital (4 gm administered intravenously). Fetuses were perfused via the left ventricle with 10% formalin in saline solution. Cochleae were decalcified by immersion in ethylenediaminetetraacetic acid (EDTA) for 5 months, embedded in paraffin, sectioned every 19 μm, stained with hematoxylin and eosin, and examined under a light microscope.

Results

Intact fetuses. In pilot studies we were unable to detect any changes in fetal activity with 5- to 30-second stimulation with a model 5C electrolarynx in either the high voltage or low voltage electrocortical state, and at any position on the maternal abdomen. The effects of stimulation with the electrolarynx were not investigated further and instead stimuli were applied with the more powerful oscillator. The clearest effect of stimulation with this oscillator was to change fetal electrocortical state and the change was principally from high voltage to low voltage (i.e., a desynchronization). Fig. 1 shows a typical polygraph record and Fig. 2 shows the incidence of a change in electrocortical state in all trials.

In trials begun in the high voltage electrocortical state the incidence of desynchronization after stimulation (84%) was much greater than that occurring spontaneously (8%) (Fig. 2). Every animal responded in at least 69% of stimulation trials. We found no evidence of habituation of this response. Thus the incidence of desynchronization was no different throughout each day and animals continued to respond over several weeks of testing. When desynchronization occurred the mean electrocortical amplitude (131 μV) during the trial was much lower than that in the preceding 2 minutes of high voltage electrocortical state (268 μV), but slightly higher (by 18%; i.e., 20 μV) than that in the spontaneous low voltage electrocortical state (Fig. 3). The latency of the stimulated low voltage electrocortical

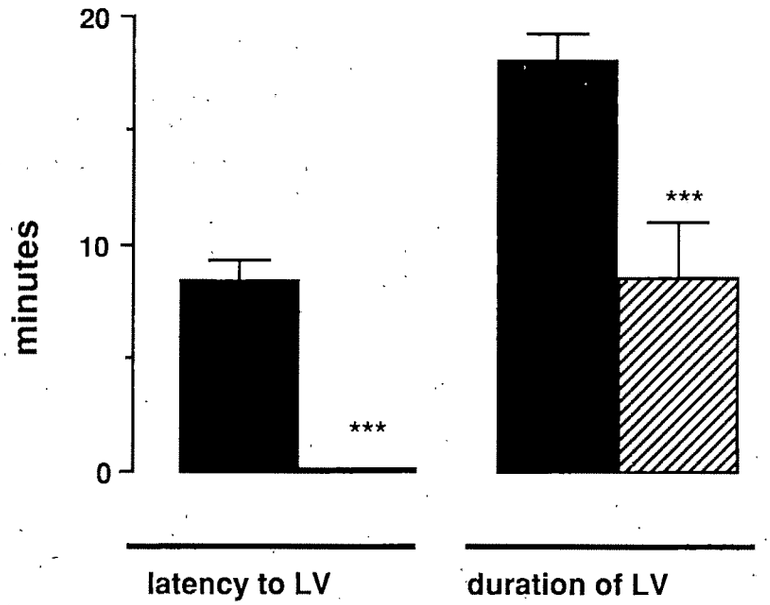

Fig. 4. Mean (±SE) latency and duration of stimulated desynchronization *(crossed bars)* or spontaneous desynchronization when it eventually occurred in no stimulation trials *(filled bars)* for trials begun in high voltage electrocortical state (n = 119 trials in four fetuses). *three asterisks*, $p < 0.001$ for stimulated vs spontaneous desynchronization. *LV*, Low voltage.

state (Fig. 4) was negligible and the mean duration of the stimulated low voltage electrocortical state (Fig. 4) was only half that of spontaneous low voltage electrocortical states.

When stimulation in high voltage electrocortical states caused desynchronization, an episode of fetal breathing and eye movement also occurred. Normally the incidence of fetal breathing movements and eye movements is greatest in low voltage electrocortical states. In four fetuses the mean incidences of fetal breathing and eye movements during induced low voltage electrocortical states (mean 0.57, SE 0.13; mean 0.45, SE 0.25) were not different from those during spontaneous low voltage electrocortical states (mean 0.49, SE 0.07; mean 0.45, SE 0.25). The incidence of nuchal activity was significantly greater during induced low voltage electrocortical states (0.78, SE 0.09) than in spontaneous low voltage electrocortical states (0.21; SE 0.06; $p < 0.01$) or spontaneous high voltage electrocortical states (0.56; SE 0.15; $p < 0.01$). Stimulation in high voltage electrocortical states produced a small but significant fall in FHR (Fig. 5) and had no effect on fetal blood pressure.

In trials begun in the low voltage electrocortical state (Fig. 2) the incidence of changes from low voltage to high voltage electrocortical states (14%) was greater than that occurring spontaneously (2%), but the effect was much less than that in trials begun in the high voltage electrocortical state. Stimulation in the low voltage electrocortical state produced no measurable effects on visceral or somatic motor activity.

Cochlear ablated fetuses. Bilateral cochlear ablations were attempted in five fetuses. After postoperative recovery the incidence, amplitude, and cyclic nature of the spontaneous electrocortical state and of spontaneous motor activity was no different from that in intact fetuses. Fig. 6 shows the incidence of desynchronization during trials in cochlear ablated fetuses. Inasmuch as the variances are dissimilar, statistical analysis by parametric methods is not appropriate, and the results from each animal are presented separately. For comparisons Fig. 6 also shows the results from similar trials in five intact fetuses (taken from Fig. 2 and presented in the same manner). In four of the five cochlear ablated fetuses, the incidence of desynchronization after stimulation was no greater than that occurring spontaneously. Stimulation also did not change visceral or somatic motor activity. Even use of the same stimulus protocol but with lower fundamental frequencies (40 to 400 Hz) and stimulation at maximum intensity did not change the electrocortical state or motor activity. In the remaining fetus, the incidence of desynchronization after stimulation was greater than that occurring spontaneously, but remained less than that in any intact fetus.

Inspection of the cochlear sections under a light microscope revealed varying degrees of damage among the five fetuses. In two fetuses there was gross damage

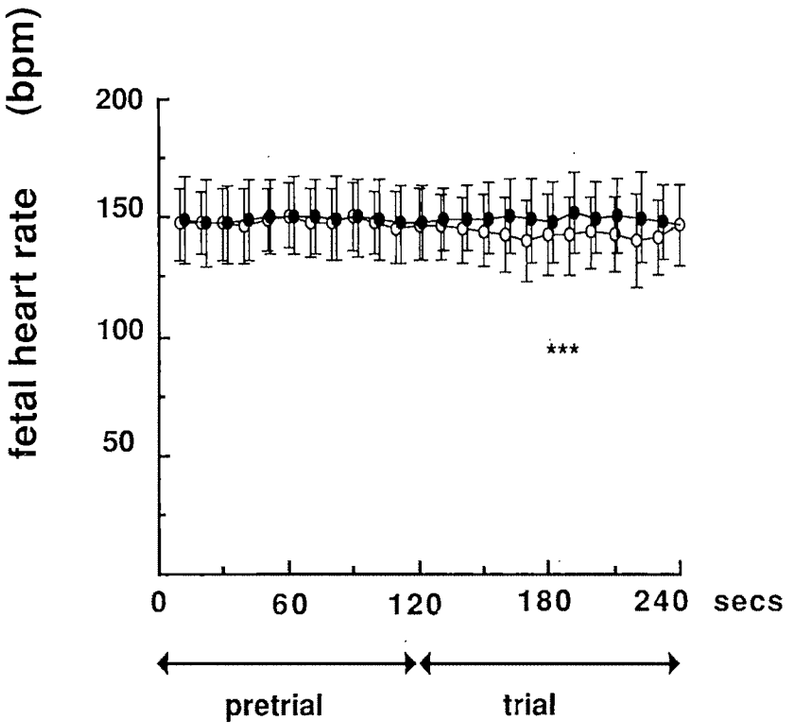

Fig. 5. Mean (±SE) FHR (beats per minute every 10 seconds) in the pretrial and trial periods with stimulation *(open circles)* or no stimulation *(filled circles)* in trials begun in high voltage electrocortical state (n = 63 trials in three fetuses). The overall mean in the stimulation trial period (145 beats/min) is significantly lower (*three asterisks*, $p < 0.001$) than that in either the stimulation pretrial period (149 beats/min) or in the nonstimulation periods (both 150 beats/min). *sec*, Seconds.

to all cochleae in one or more turns. Both these fetuses did not respond to vibroacoustic stimulation. The remaining three fetuses had partial damage in all cochleae in one or more turns and these three could not be distinguished solely on the basis of cochlear damage. Two of these fetuses did not respond to stimulation, whereas in a third the incidence was greater than that occurring spontaneously, but still less than that in any intact fetus.

Comment

We were able to change electrocortical state by stimulation with a powerful oscillator, the most consistent effect being electrocortical desynchronization. The intensity of vibroacoustic stimuli from a point source on the maternal abdomen may vary at different points inside the amniotic cavity. This might influence the incidence of fetal responses, especially if the stimulus is detected by sensory apparatus located in the head. It appears unlikely that consistent movements of the fetal head away from the stimulus influenced the incidence of responses because fetal responsiveness did not decline during each day or over several weeks of testing. It is possible that the fetus with the lowest incidence of responses (69%) was always further away from the stimulus than was the highest responder (100%). Nevertheless, the lowest incidence is still so much greater than the maximum incidence of responses by chance (12%) that a disadvantageous position would clearly not prevent a fetus from responding to this stimulus.

Our pilot studies are consistent with earlier findings[7] that 45-minute stimulation of fetal sheep with the model 5C electrolarynx does not alter fetal electrocortical state. Nevertheless, with the use of intrauterine hydrophones the sound intensity produced by the electrolarynx (135 dB) is considerably higher than that of background noise (55 to 65 dB) in utero.[6] Because 45 minutes of stimulation with the electrolarynx increased glucose uptake in the fetal central nervous system,[7] it is likely that this stimulus is detected by the peripheral sensory apparatus. However, because 45 minutes of such stimulation failed to change the electrocortical state or motor activity,[7] it is likely that the afferent input is of relatively low intensity. We do not know the intensity of the stimulus produced by our oscillator in the amniotic fluid. However, the intensity of the afferent input it produces is likely to be relatively greater than that produced by the electrolarynx. This is because our

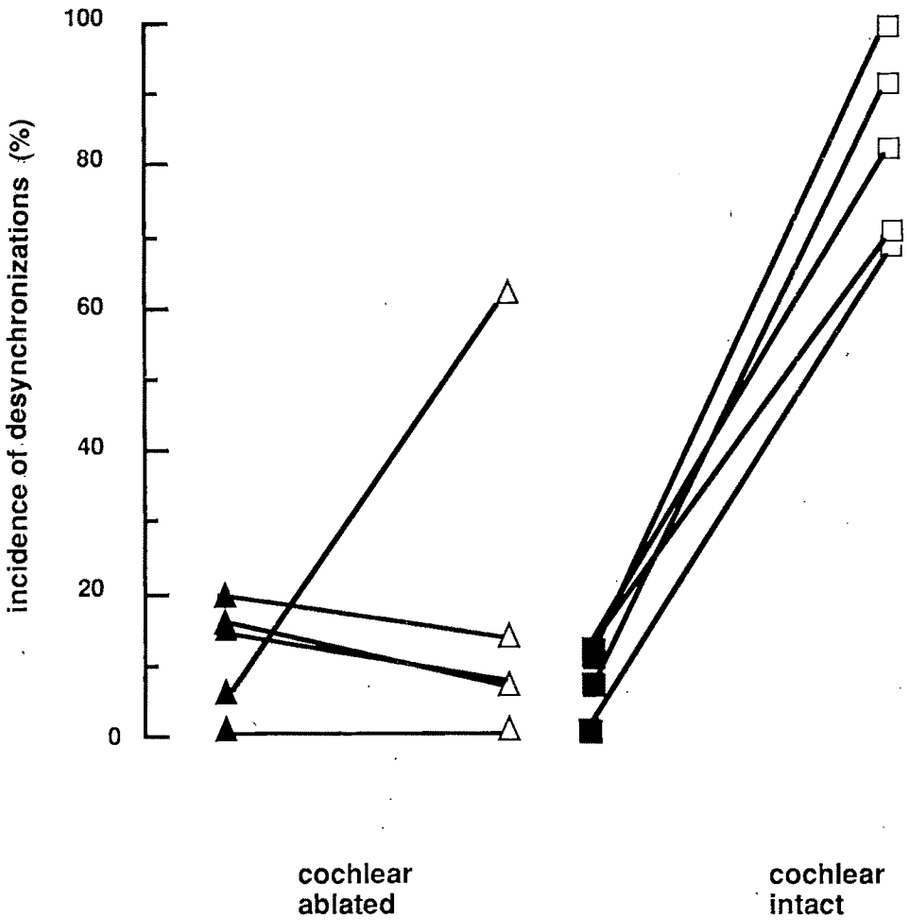

Fig. 6. The incidence of desynchronization in stimulation *(open characters)* and no stimulation trials *(filled characters)* begun in high voltage electrocortical state in five cochlear ablated fetuses (n = 120 trials), and five intact fetuses (n = 155 trials, replotted from Fig. 2).

oscillator was 55 times more powerful and because our oscillator did produce changes in fetal behavior, unlike the electrolarynx.[7] Furthermore, the responses to stimulation with our oscillator are very similar to the responses made by unanesthetized fetal sheep when given direct and intense electric stimulation in utero. Application[15] of 50-volt stimuli for 5 minutes through electrodes chronically implanted into fetal brachial nerve produced almost identical effects on electrocortical state and nuchal muscle activity, with no consistent change in FHR or blood pressure.

The induced low voltage electrocortical state was accompanied by a normal incidence of fetal breathing and eye movements. Its duration and amplitude, however, were 50% shorter and 18% higher than those of the spontaneous low voltage state, and it was accompanied by an abnormally high incidence of nuchal activity. With the use of Fourier analysis on fetal sheep, two transitional electrocortical patterns have recently been described mathematically[16] in addition to the two obvious high voltage and low voltage electrocortical states that are accompanied by characteristic fetal-breathing and eye-movement patterns. It is possible that our induced low voltage electrocortical state contains relatively more of such transitional activity. It is not known whether the spontaneous low voltage state in utero is a unique intrauterine state or is the same as one of the postnatal states of wakefulness or rapid eye movement sleep. Definitions of wakefulness usually require demonstration of purposeful activity,[8] which are not easily made in utero, and sleep needs to be distinguished from a comatose state. Wakefulness and two states of sleep have been suggested to occur in fetal sheep delivered into a warm bath with intact umbilical cords.[8] In that study, however, it was not shown whether any of those three states were the same as the high

voltage and low voltage states observed in utero. For these reasons we have not given a title to the low voltage state induced by vibroacoustic or electrical stimulation.

In fetal sheep after bilateral cochlear ablation, a large reduction in basal glucose uptake in brainstem auditory nuclei has been described.[17] Whereas spontaneous fetal behavior appeared normal, smaller reductions in basal glucose uptake were also observed in many other areas of the fetal central nervous system. It was speculated that cochlear ablation might result in diffuse inactivation of the fetal central nervous system. In all our fetuses with bilateral cochlear ablation we can confirm that spontaneous electrocortical state and visceral and somatic motor activity were normal. Thus the proposed loss of central nervous system activation from auditory structures produces no obvious changes in spontaneous fetal activity. In four of five fetuses with cochlear ablation vibroacoustic stimulation failed to produce the changes in electrocortical state or motor activity that were seen in intact fetuses. In two of these four fetuses there was gross damage in all cochleae and in two there was partial damage. The fifth fetus responded more than expected by chance but less than any intact fetus. There was no obvious difference between the partial cochlear damage in this fetus and that in the two that did not respond, so we are unable to define precisely the damaged cochlear structures responsible for this reduced response. These results nevertheless indicate that in fetal sheep the peripheral auditory apparatus is necessary for the detection of vibroacoustic stimuli.

The initial aim of these experiments was to test whether vibroacoustic stimulation of fetal sheep could produce the same effects as those previously described in human fetuses. In man, the electrolarynx produces a mean increase of 11 beats/min in FHR, with a change apparent up to 1 hour afterward.[1] In sheep, the fact that the electrolarynx increases glucose uptake in the central nervous system indicates that the stimulus is detected, but stimulation with the electrolarynx appears to produce no effect on FHR or behavior. Both our more intense auditory stimulus and direct electric stimulation of the brachial nerve used by others[15] caused a change in electrocortical state with concomitant changes in somatic motor activity, although the overall effect on FHR was negligible. This negligible effect on heart rate cannot be explained by a complete lack of sensory input to cardiovascular efferent centers in the sheep because sudden elevation of fetal blood pressure will induce a reflex fall in FHR.[18] Thus the difference in heart rate response between the two species appears to have its origin in the central nervous system after detection of the stimulus.

We are grateful to Mrs. Jean McGowan, Department of Audiology, Royal Berkshire Hospital, for the electrolarynx, to Dr. A. Pretlove, Department of Engineering, University of Reading, for the oscillator, and to Mr. R. Coe, Department of Applied Statistics, University of Reading.

Magnesium sulfate–induced relaxation of uterine arteries from pregnant and nonpregnant patients

Sharon H. Nelson, PhD, and Maya S. Suresh, MD
Galveston, Texas

The effects of magnesium sulfate at different concentrations were investigated in isolated rings of uterine arteries from pregnant and nonpregnant patients. Addition of magnesium sulfate (0.5 to 9.6 mmol/L) to the suffusion medium containing the normal concentration of 1.2 mmol/L magnesium sulfate produced concentration-dependent relaxation of norepinephrine (1 μmol/L)–induced or potassium chloride (35 mmol/L)–induced contractions. Magnesium sulfate was about three times more potent in causing inhibition of potassium chloride–induced contractions in uterine arteries from pregnant patients than in those from nonpregnant patients. The concentrations that inhibited 50% of the contraction induced by potassium chloride were 0.6 ± 0.2 mmol/L (n = 4) in the arteries from pregnant patients and 1.6 ± 0.2 mmol/L (n = 4) in the arteries from nonpregnant patients. At high concentrations (4.8 and 9.6 mmol/L), magnesium sulfate also was more potent in inhibiting norepinephrine-induced contractions in arteries from pregnant women than in arteries from nonpregnant women. The magnesium sulfate–induced relaxation was almost completely inhibited by calcium chloride (2 mmol/L) added to the suffusion medium containing the normal concentration of 2.5 mmol/L calcium chloride but was not affected by indomethacin (5 μmol/L), methylene blue (10 μmol/L), or removal of the endothelium. The results show that magnesium sulfate, at therapeutic blood concentrations, acts as a potent dilator of human uterine arteries, especially those from pregnant patients. The results are consistent with the view that magnesium sulfate may facilitate uteroplacental perfusion. (Am J Obstet Gynecol 1991;164:1344-50.)

Key words: Vascular smooth muscle, norepinephrine-induced contraction, potassium chloride–induced contraction, calcium, endothelium-independent vasodilation

Magnesium sulfate, when it is used parenterally as an adjunct in the management of certain hypertensive disorders during pregnancy, has been reported to produce a slight increase in uteroplacental blood flow in pregnant sheep[1] and to cause an increase in uterine artery blood flow secondary to a selective decrease in uterine artery vascular resistance in the pregnant monkey.[2] Although resistance to flow is usually thought to involve small arteries and arterioles, uterine vascular resistance in pregnant patients may occur in the larger uterine arteries (uterine and radial), because the myometrial resistance vessels (spiral arteries and arterioles) lose the smooth muscle layer early in pregnancy.[3] One objective of the present study was to determine if pregnancy alters the dilator potency of magnesium sulfate in the uterine artery.

The vasodilator activity of magnesium sulfate, which is well documented in a number of other blood vessel preparations,[4] is generally thought to be due to interference with excitation-contraction coupling by competition with calcium.[4-7] However, other mechanisms of action for magnesium sulfate–induced vasodilation have been considered, e.g., the release or action of vasodilator substances such as endothelium-derived relaxing factor[7, 8] or prostacyclin.[4, 9, 10] A second objective of this study was to determine whether magnesium sulfate–induced dilatation of the isolated uterine arteries involves a calcium antagonist action or the release of an endogenous relaxing factor. Preliminary reports of these studies have been published previously.

Material and methods

Specimens of the ascending branch of the uterine artery were obtained from patients undergoing hysterectomy for various medical reasons. (Use of uterine arteries from patients undergoing hysterectomy was approved by the Institutional Review Board for the University of Texas Medical Branch, Galveston.) Nonpregnant patients (n = 9) varied in age from 31 to 46 years and were in different phases of the menstrual cycle. Immediately postpartum (pregnant) patients (n = 5) varied in age from 23 to 37 years. The gestations were term.

The nonpregnant patients generally received diazepam or morphine sulfate and atropine, scopolamine, or glycopyrrolate for preanesthetic medication. The pregnant patients received Bicitra Willen antacid for aspiration prophylaxis. Anesthesia was induced with thiopental sodium and maintained with nitrous oxide–oxygen and either halothane, enflurane, or isoflurane.

Immediately after hysterectomy, sections of the uterus containing the uterine arteries were placed in gassed (95% oxygen and 5% carbon dioxide) Krebs-bicarbonate solution and taken to the laboratory. The preparation of isolated arterial rings and the suffusion techniques used have been described in detail previously.[11, 12] In brief, rings (2 mm in length) were prepared from the uterine artery and mounted between two tungsten wires in a 5 ml volume suffusion chamber. Changes in isometric tension were measured by means of a force-displacement transducer (Statham) connected to the upper mounting wire and recorded on a Gould recorder (2400 Brush Model).

After the arteries were mounted in the chambers, they were suffused continuously with gassed (95% oxygen and 5% carbon dioxide) Krebs-bicarbonate solution at a flow rate of 4 ml/min delivered by a peristaltic pump (Gilson Instruments). The Krebs-bicarbonate solution had the following composition: (sodium chloride, 119 mmol/L; sodium bicarbonate, 25 mmol/L; potassium chloride, 3.6 mmol/L; magnesium sulfate, 1.2 mmol/L; potassium phosphate, 1.2 mmol/L; calcium chloride, 2.5 mmol/L; glucose, 11 mmol/L; ascorbic acid, 0.005 mmol/L; and disodium ethylenediaminetetraacetate, 0.03 mmol/L. The bath solution was maintained at 37° C and had a pH of 7.4. The drugs were administered in the inflowing suffusion fluid.

The preparation was allowed a stabilization period of 1 to 2 hours before the experiment began. During that time, basal tension was adjusted repeatedly until the resting tension became stable at 1 gm. (One gram has been found to be the optimal resting tension for human uterine arteries.) After this stabilization period, the contractile responses to norepinephrine at various concentrations were reproducible for several hours.

To determine the effect of magnesium sulfate on resting tension, magnesium sulfate (4.8 mmol/L) was added for 15 minutes to the arterial ring suffused with Krebs-bicarbonate solution containing the normal concentration of magnesium sulfate (1.2 mmol/L). The concentration of 4.8 mmol/L was selected because it produced near-maximal relaxation of precontracted arteries. At least 60 minutes was allowed to wash out the elevated concentration of magnesium sulfate before other studies were done in the same arterial ring.

Contractile responses induced by norepinephrine and potassium chloride were studied in rings from the same artery. The uterine arteries in Krebs solution containing the normal concentration of magnesium sulfate (1.2 mmol/L) were contracted by norepinephrine (1 μmol/L) or by potassium chloride (35 mmol/L). These concentrations were found in previous studies to elicit about 50% to 60% of the maximal contractile responses to these drugs in uterine arteries from pregnant or nonpregnant patients.[12] In the studies with potassium chloride, phentolamine (1 μmol/L) was present in the Krebs solution to antagonize the action of any norepinephrine released from the sympathetic nerve endings by potassium chloride. When the contractile response to norepinephrine or potassium chloride was stable (after 10 to 15 minutes), various experimental protocols were used to examine the effects and mechanism of action of magnesium sulfate.

Magnesium sulfate, at increasing concentrations from 0.5 to 9.6 mmol/L, was added to the contracted artery. Each concentration of magnesium sulfate was administered from 10 to 15 minutes or until the contraction reached a steady state. Throughout these studies magnesium sulfate was administered in Krebs-bicarbonate solution that contained the normal magnesium sulfate concentration of 1.2 mmol/L.

Magnesium sulfate (2.0 mmol/L) was added for 15 minutes to the contracted artery. The concentration of 2 mmol/L was selected because it produced about 50% to 70% inhibition of the contractions induced by norepinephrine. Magnesium sulfate was then washed out until the contractile response to norepinephrine was regained; subsequently, norepinephrine was washed out until the baseline tension returned. This procedure was termed the magnesium sulfate–relaxation protocol. The tissue was then suffused for 20 minutes with a given concentration of indomethacin, to inhibit prostaglandin synthetase, or methylene blue, to prevent the effect of endothelium-derived relaxing factor on soluble guanylate cyclase. Norepinephrine, in the presence of the blocker, was again administered; the magnesium sulfate–relaxation protocol followed. Only one concentration of magnesium sulfate was used in these studies because of the length of time the experiment required.

In studies on the dependency on an intact endothelium for the vasodilatory effect of magnesium sulfate, the magnesium sulfate–relaxation protocol was followed. Subsequently, the endothelium was disrupted mechanically,[13] and a stabilization period of about 30 minutes was allowed before the magnesium sulfate–relaxation protocol was repeated. Successful removal of endothelial cells from the rings was confirmed by histologic examination of the intimal surface with a silver-staining technique.[13] Uterine arteries that had not been through the endothelium removal procedure were also examined by this technique. Control exper-

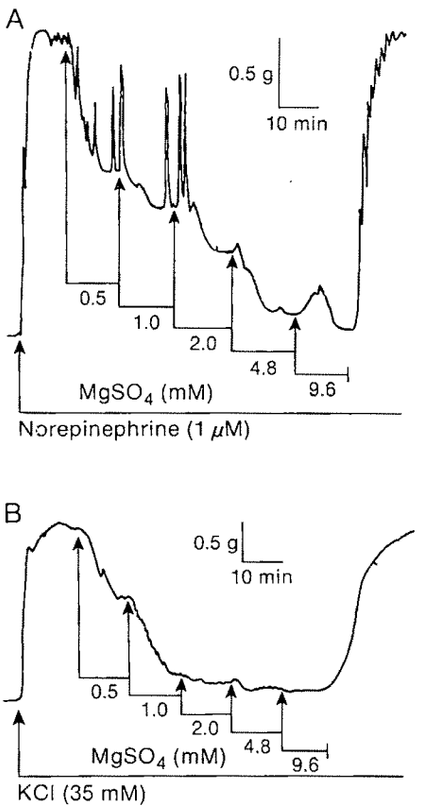

Fig. 1. Inhibition by magnesium sulfate *(MgSO4)* of norepinephrine-induced **(A)** and potassium chloride *(KCl)*–induced **(B)** contractions of isolated uterine artery from a pregnant patient. Concentrations of magnesium sulfate are those added to Krebs solution containing 1.2 mmol/L magnesium sulfate. Each experiment was carried out on a different arterial ring from the same uterine artery. Note that the vasorelaxant effect of magnesium sulfate was readily washed out and that it was more potent when inhibiting a potassium chloride–induced contraction. Endothelium was present in both rings.

iments were performed using the magnesium sulfate–relaxation protocol without the presence of antagonist or blocker or without the disruption of the endothelium.

To investigate a magnesium-calcium interaction in the uterine artery, the magnesium sulfate–relaxation protocol was followed for the control response to magnesium sulfate. The tissue was then suffused for 20 minutes with Krebs solution before norepinephrine was again administered. After the contractile response to norepinephrine stabilized, the concentration of calcium chloride in the Krebs solution was increased to 4.5 mmol/L and allowed to suffuse for 10 to 15 minutes. Magnesium sulfate (2 mmol/L) was then added for 15 minutes in the presence of the elevated concentration of calcium chloride.

Inhibition by magnesium sulfate of the norepinephrine-induced or potassium chloride–induced contraction was expressed as a percentage of the contraction before magnesium sulfate, at various concentrations, was administered. Norepinephrine-induced tonic contraction was often associated with phasic contractions (drug-induced oscillatory activity). When this oscillatory activity occurred, the lowest developed tension during the rhythmic activity was taken as the response; i.e., the amplitude of the rhythmic activities was not included in the measurements. Data are presented as mean values ± SE for grams of contraction, percent inhibition by various concentrations of magnesium sulfate, and the concentrations that inhibited the norepinephrine-induced or potassium chloride–induced contraction by 50%. The values were obtained from graphs of data from each experiment. Results were analyzed by means of a nonparametric analysis of variance test (Wilcoxon). Data obtained with a given protocol in uterine arteries from nonpregnant patients were compared with data obtained by the same protocol in uterine arteries from pregnant patients. A p value <0.05 was considered significant.

All stock solutions and serial dilutions made in Krebs-bicarbonate solution were prepared shortly before the start of each of the experiments. The following drugs were used and were obtained from Sigma Chemical Co.: (-)-arterenol bitartrate, indomethacin, and methylene blue.

Results

The mean arterial blood pressure of the nonpregnant patients was 95.3 ± 5.6 mm Hg (range, 83 to 110 mm Hg; $n = 9$). The mean arterial blood pressure of the pregnant patients was 91.3 ± 3.0 mm Hg (range, 87 to 97 mm Hg; $n = 5$).

After the uterine arteries were mounted in the perfusion chamber and the resting tension was applied, tension gradually increased for 5 to 15 minutes, then decreased. The decrease in tension was often associated with some spontaneous contractile activity. After the baseline stabilized, there was, as a general rule, little or no spontaneous contractile activity. In the uterine arteries from either pregnant patients ($n = 3$) or nonpregnant patients ($n = 3$), addition of magnesium sulfate (4.8 mmol/L) had no demonstrable effect on the resting tension.

In order to examine the relaxing effect of magnesium sulfate in uterine arteries, tone was first induced by either norepinephrine (1 μmol/L) or potassium chloride (35 mmol/L). Developed tension induced by norepinephrine (1 μmol/L) was not significantly different in arteries from pregnant patients (2.4 ± 0.2 gm, $n = 5$) and those from nonpregnant patients (2.7 ± 0.3 gm, $n = 9$), nor was there any significant difference in the magnitude of contraction produced

by potassium chloride (35 mmol/L) in arteries from pregnant patients (3.5 ± 2.1 gm, $n = 4$) and nonpregnant patients (3.2 ± 1.1 gm, $n = 4$). Magnesium sulfate (0.5 to 9.6 mmol/L), added to Krebs solution containing the normal concentration of 1.2 mmol/L magnesium sulfate, produced concentration-dependent relaxation of contractions induced either by norepinephrine or by potassium chloride in arteries from both pregnant (Fig. 1) and nonpregnant patients. Besides inhibiting the norepinephrine-induced tonic contraction in the uterine arteries, magnesium sulfate also inhibited the norepinephrine-induced phasic contractions. The results from experiments similar to those shown in Fig. 1 are summarized in Fig. 2. Magnesium sulfate at low concentrations (0.5 to 2 mmol/L) produced similar inhibition of the norepinephrine-induced contractions in arteries from pregnant and nonpregnant patients (Fig. 2, *A*). The concentrations that inhibited norepinephrine-induced contractions by 50% were 1.1 ± 0.3 mmol/L ($n = 5$) and 0.8 ± 0.4 mmol/L ($n = 9$) in arteries from pregnant and nonpregnant patients, respectively. However, at higher concentrations (4.8 to 9.6 mmol/L) magnesium sulfate produced a significantly greater inhibition of the norepinephrine-induced contraction in arteries from pregnant patients than in those from nonpregnant patients. Magnesium sulfate (4.8 mmol/L) produced nearly complete relaxation of the norepinephrine-induced contraction in the arteries from pregnant patients. In contrast, magnesium sulfate, at all concentrations used in these studies, produced a significantly greater inhibition of potassium chloride–induced contraction in the arteries from pregnant patients than in those from nonpregnant patients. (Fig. 2, *B*). The concentration of magnesium sulfate needed to inhibit potassium chloride–induced contractions by 50% in arteries from pregnant patients (0.6 ± 0.2 mmol/L, $n = 4$) was less than half that required in arteries from nonpregnant patients (1.6 ± 0.2 mmol/L, $n = 4$).

Calcium chloride (2 mmol/L) had little or no effect on the contractile response to norepinephrine but prevented magnesium sulfate (2 mmol/L)–induced inhibition of norepinephrine-induced contraction (Figs. 3 and 4). Similarly, calcium chloride (2 mmol/L) antagonized magnesium sulfate (2 mmol/L)–induced relaxations of potassium chloride (35 mmol/L)–induced contractions in arteries from both pregnant and nonpregnant patients. Magnesium sulfate–induced relaxations of potassium chloride–induced contractions in arteries from pregnant and nonpregnant patients were, respectively, 92% ± 2% ($n = 4$) and 70% ± 8% ($n = 4$) in the absence of calcium chloride (2 mmol/L) and 9% ± 5% ($n = 4$) and 4% ± 7% ($n = 4$) in the presence of calcium chloride. After a 30-minute washout of the elevated concentration of calcium chloride,

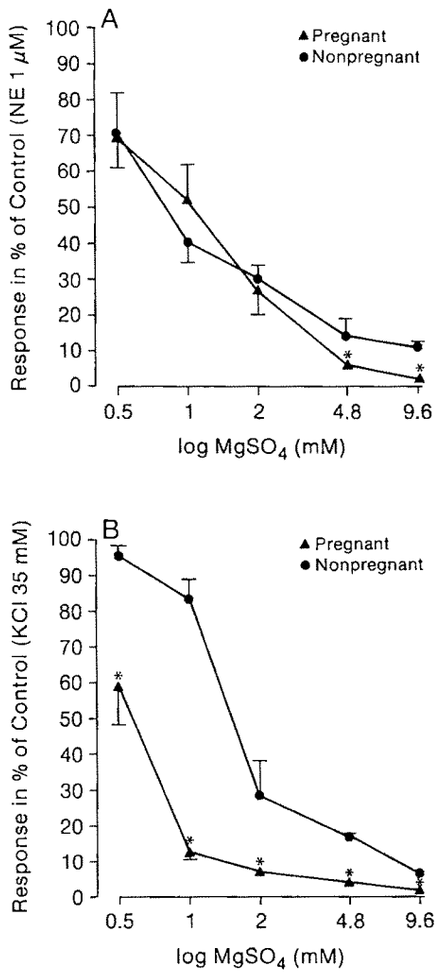

Fig. 2. Concentration-dependent relaxant effects of magnesium sulfate in human uterine arteries contracted by norepinephrine **(A)** and potassium chloride **(B)**. Arteries were from pregnant (▲——▲) and nonpregnant (●——●) patients. Concentrations of magnesium sulfate are those added to Krebs solution containing 1.2 mmol/L magnesium sulfate. Each concentration was given for 10 to 15 minutes. Responses are expressed as percent of control contractile response to norepinephrine (1 μmol/L) **(A)** or potassium chloride (35 mmol/L) **(B)**. Data are means ± SE ($n = 4$ to 9). *Asterisk*, $p < 0.05$.

magnesium sulfate again induced relaxation of the contractions produced by norepinephrine or potassium chloride. Higher concentrations of calcium chloride (3 to 4 mmol/L) were not used in the study because preliminary studies showed that these concentrations inhibited norepinephrine-induced or potassium chloride–induced contractions.

To test for possible mediators of the magnesium sulfate–induced relaxation of uterine arteries, magnesium sulfate (2 mmol/L)–induced inhibition of contractions produced by norepinephrine (1 μmol/L) was

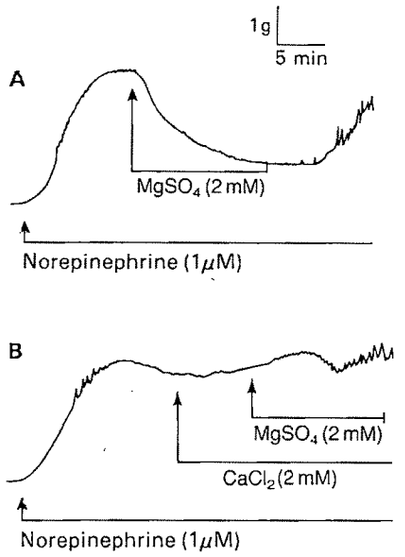

Fig. 3. Calcium chloride antagonism of magnesium sulfate–induced relaxation in uterine artery from a nonpregnant patient. Magnesium sulfate was administered for about 15 minutes in **A** and **B.** Concentration of magnesium sulfate is that added to Krebs solution containing 1.2 mmol/L magnesium sulfate. Concentration of calcium chloride reflects addition of 2 mmol/L calcium chloride to Krebs solution containing 2.5 mmol/L calcium chloride. Preliminary studies showed that 2 mmol/L calcium chloride administered during norepinephrine administration gave the best inhibition of magnesium sulfate–induced relaxation. (Modified from Anesthesiology 1987;67:A636.)

determined in the absence and the presence of indomethacin (5 μmol/L), an inhibitor of cyclooxygenase, methylene blue (10 μmol/L), an inhibitor of soluble guanylate cyclase, and in the presence and then the absence of endothelium. As shown in Fig. 4, the treatments with indomethacin or methylene blue or with removal of the endothelium did not significantly alter the magnesium sulfate–induced relaxation. There was also a lack of effect of these treatments on magnesium sulfate (2 mmol/L)–induced inhibition of contractions produced by potassium chloride or on the potassium chloride–induced contraction itself.

Comment

Our results show that magnesium sulfate acts as a potent dilator in human uterine arteries. Furthermore, we have shown that it is about three times more potent when inhibiting potassium chloride–induced contractions in uterine arteries from pregnant patients than in uterine arteries from nonpregnant patients. At concentrations higher than the value needed for 50% inhibition, magnesium sulfate is also more potent in inhibiting norepinephrine-induced contractions in arteries from pregnant patients than in arteries from nonpregnant patients.

It is recognized that some of the anesthesia-related drugs have prolonged vascular actions, but it was assumed that continuous suffusion of the tissue preparations removed most of the drugs. Furthermore, the fact that the contractile responses to norepinephrine or potassium chloride did not change during the experiments implies either that the anesthesia-related drugs were washed out before commencement of the experiment or that any residual effects of the drugs did not affect the contractile responses to norepinephrine or potassium chloride.

The results show that calcium chloride, at a concentration higher than that in the Krebs solution, almost completely prevented the magnesium sulfate–induced relaxation. These results suggest that magnesium sulfate competes with extracellular calcium for transport into the cell. A caveat to this interpretation of the results is that only single concentrations of calcium chloride and magnesium sulfate were used for the studies. However, our results using human uterine arteries are consonant with the results from numerous other investigations that suggest that magnesium sulfate exerts a relaxing action in blood vessels by interfering with calcium permeability in the cellular membrane.[1-7]

It is well known that contractions of blood vessels induced by potassium chloride (depolarization) are dependent on influx of extracellular calcium through voltage-dependent calcium channels.[14] Organic calcium antagonists, such as verapamil, which block voltage-dependent calcium channels, are especially effective in inhibiting the vasoconstrictor responses to potassium chloride. In this study the findings that magnesium sulfate blocked potassium chloride–induced contractions suggest that magnesium sulfate, like verapamil, acts as a calcium antagonist. It is also well known that contractions induced by norepinephrine are dependent on both release of intracellular calcium and influx of extracellular calcium through receptor-operated and voltage-dependent calcium channels.[14] We have previously reported that verapamil is significantly more potent in inhibiting norepinephrine-induced contractions in arteries from pregnant women than in arteries from nonpregnant women. The results indicated that calcium from extracellular fluid via voltage-dependent calcium channels played a greater role in mediating contraction in arteries from pregnant women,[15] whereas intracellular calcium release played a greater role in mediating contraction in arteries from nonpregnant women. The results of the present study that show no significant difference in the potency for magnesium sulfate acting against norepinephrine-induced contractions in arteries from pregnant and nonpreg-

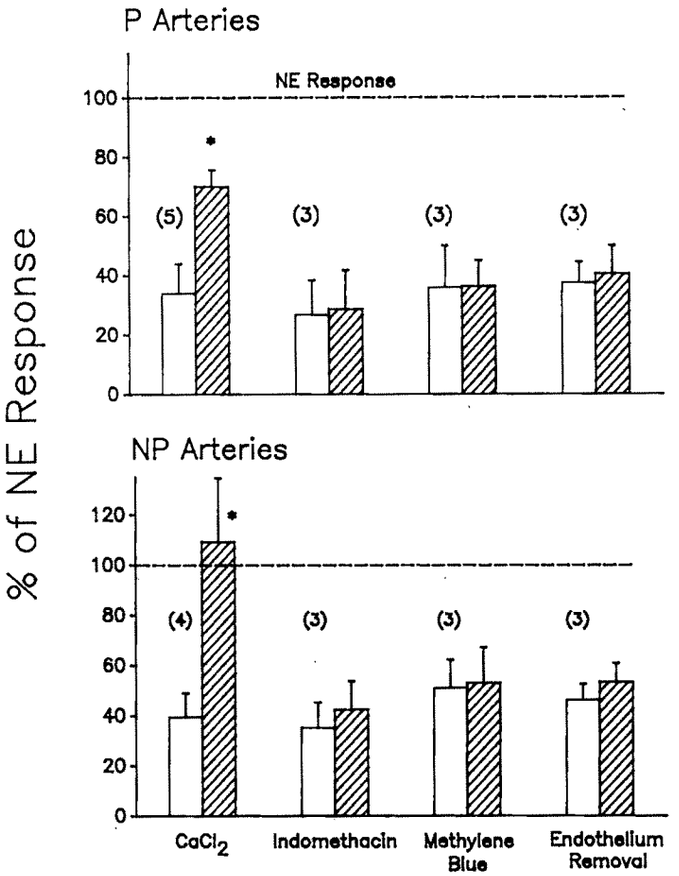

Fig. 4. Effects of various treatments on magnesium sulfate–induced relaxation of contractions produced by norepinephrine *(NE)* in isolated human uterine arteries. *P*, Pregnant; *NP*, nonpregnant. Data are shown as mean ± SE in percent of response to norepinephrine (1 μmol/L) in presence of increased concentration of magnesium sulfate (2 mmol/L) compared with response to norepinephrine (*dotted line*, 100%) in absence of increased concentration of magnesium sulfate. Concentration of 1.2 mmol/L magnesium sulfate is normally present in Krebs solution. *Open bars* represent control magnesium sulfate–induced relaxation of norepinephrine-induced contraction, and *hatched bars* represent magnesium sulfate–induced relaxation in presence of treatment. Treatments included calcium chloride *($CaCl_2$)* (2 mmol/L), indomethacin (5 μmol/L), methylene blue (10 μmol/L), and endothelium removal. Number of experiments is indicated in parentheses. *Asterisk*, Significantly different, $p > 0.05$.

nant patients indicate that magnesium sulfate may interfere with sites involved with intracellular calcium release, as well as with voltage-dependent calcium channels.

Our studies show that magnesium sulfate–induced relaxation does not involve the release of vasodilator prostanoids in the isolated uterine artery. Similar findings have been reported and show that magnesium sulfate–induced dilatation of arterioles or venules in the rat cremaster muscle is not mediated by vasodilator prostanoids.[4] However, other studies report that magnesium sulfate releases vasodilator prostaglandins from endothelial cells of the human umbilical vein[10] and increases the levels of 6-keto-prostaglandin $F_{1\alpha}$ in the urine of humans.[9]

Results from our studies with the use of arterial rings with the endothelium removed or in the presence of methylene blue demonstrate that magnesium sulfate–induced relaxation of uterine arteries from pregnant and nonpregnant patients is independent of the presence of an intact endothelium and does not involve the release of endothelium-derived relaxing factor. Sjogren and Edvinsson[7] also showed that magnesium sulfate–induced relaxation in feline femoral arteries was independent of the presence of endothelium. We have shown previously that the endothelium and

endothelium-derived relaxing factor may indeed play a role in mediating vasodilation induced by drugs such as acetylcholine in uterine arteries from pregnant patients but not in those from nonpregnant patients;[16] whereas nitroprusside, like magnesium sulfate, produces dilation in the presence or absence of endothelium.[12]

Most patients treated with short-term intravenous magnesium sulfate for preeclampsia-eclampsia commonly have plasma magnesium levels (2 to 3 mmol/L or 4 to 6 mEq/L) that are even higher than the 50% inhibition values (0.6 to 1.8 mmol/L or 1.2 to 3.6 mEq/L) for magnesium sulfate determined in our study. Our results suggest that in patients with preeclampsia administration of magnesium sulfate not only helps to prevent convulsions but also causes a dilatation of constricted uterine arteries and thus enhances, or at least maintains, uterine blood flow to the potentially compromised fetus. This suggestion is supported by studies showing that magnesium sulfate produces a slight increase in uteroplacental blood flow in pregnant sheep[1] and causes an increase in uterine artery blood flow, which is secondary to a selective decrease in uterine artery resistance, despite a lack of effect on cardiac output in the pregnant monkey.[2] Our results further suggest that magnesium sulfate, when given as a tocolytic agent to patients in preterm labor, not only relaxes the uterine muscle but also decreases uterine vascular resistance, thereby increasing uterine blood flow.

In summary, our findings indicate that magnesium sulfate, at concentrations that are considered therapeutic, is a direct-acting, endothelium-independent vasodilator of isolated uterine arteries from pregnant and nonpregnant patients.

We acknowledge the late Dr. David Bee for his assistance with the statistics.

Regulation of the immune response to *Candida albicans* by monocytes and progesterone

Aliza Kalo-Klein, PhD, and Steven S. Witkin, PhD
New York, New York

Recurrent vaginal infections caused by *Candida albicans* are associated with decreased cell-mediated immune responses. We report that circulating progesterone levels and variations between persons in the activity of their monocytes are two of the factors that influence the extent of lymphocyte proliferation in response to *C. albicans*. With the use of peripheral blood mononuclear cells from five men and four women, removal of the monocytes increased the lymphocyte response to *C. albicans* antigens in eight persons. The percentage increase in proliferation was inversely proportional to the proliferative response observed when the monocytes were present, suggesting that differences existed between persons in the ability of their monocytes to down regulate the response. An approximate 50% decrease in *C. albicans*–induced lymphocyte proliferation was observed in the presence of luteal-phase levels (25 ng/ml), as opposed to proliferative-phase levels (0.15 ng/ml) of progesterone. Monocyte removal obviated the ability of 25 ng/ml progesterone to inhibit this response, suggesting that progesterone inhibited lymphocyte proliferation through a monocyte-dependent mechanism. Thus fluctuations in a woman's monocyte activity in response to genetic, hormonal, or environmental factors may influence her ability to mount an effective cell-mediated immune response to *C. albicans*. (AM J OBSTET GYNECOL 1991;164:1351-4.)

Key words: *Candida albicans,* progesterone, monocytes, vaginitis, cell-mediated immunity

The proliferation of *Candida albicans* in the human vagina is inhibited primarily if not entirely by the cell-mediated immune system.[1] Defects in cell-mediated immunity[2, 3] and abnormal monocyte responses[4] have been associated with recurrences of *Candida* vaginitis. Specifically, the abnormal production of prostaglandin E_2 in response to *C. albicans* by monocytes from women susceptible to recurrent vaginitis leads to an inhibition of the immune response which limits the growth of this organism.[4] Furthermore, prostaglandin E_2 also promotes the formation of germ tubes by yeast forms of *C. albicans,*[5] thereby providing the organism with the capacity to invade mucosal epithelia[6] and initiate a clinical infection. Germ tube formation is inhibited by interferon-γ,[5] a product of activated T-lymphocytes.

Recent evidence has also shown that the cellular immune response to *C. albicans* is decreased during the luteal phase of the menstrual cycle, coinciding with the time when the incidence of *Candida* vaginitis is increased.[7] This indicates that fluctuations in hormone levels may also modulate susceptibility to *Candida* infection.

In this investigation, we examined directly the effects of monocyte removal and progesterone addition on the in vitro lymphocyte proliferative response to *C. albicans.*

Material and methods

Subjects. Subjects were five men and four women of reproductive age with normal 28- to 30-day menstrual cycles, no history of *Candida* vaginitis, and negative for *Candida* on vaginal cultures. All were in good health and not taking any medication at the time of the study. Two of the women were in the second week and two were in the fourth week of their cycles.

Peripheral blood mononuclear cells. Peripheral blood mononuclear cells were isolated from heparinized blood by Ficoll-Hypaque gradient centrifugation. Monocytes were removed by adherence to plastic dishes as described previously.[4] Briefly, peripheral blood mononuclear cells (5×10^6/ml) in Roswell Park Memorial Institute 1640 medium containing 10% heat-inactivated autologous serum, were plated on 60 mm^2 plastic Petri dishes, incubated at 37° C in a 5% carbon dioxide incubator for 60 minutes, and the nonadherent cells removed with a sterile pipette. Monocyte contamination of the nonadherent cell fraction was routinely <5%.

Lymphocyte proliferation. To measure lymphocyte proliferation, 2×10^5 peripheral blood mononuclear cells or nonadherent cells were added to wells of a microtiter plate in Roswell Park Memorial Institute 1640 medium containing 25 mm/L HEPES buffer, L-glutamine, penicillin (100 U/ml), streptomycin (100

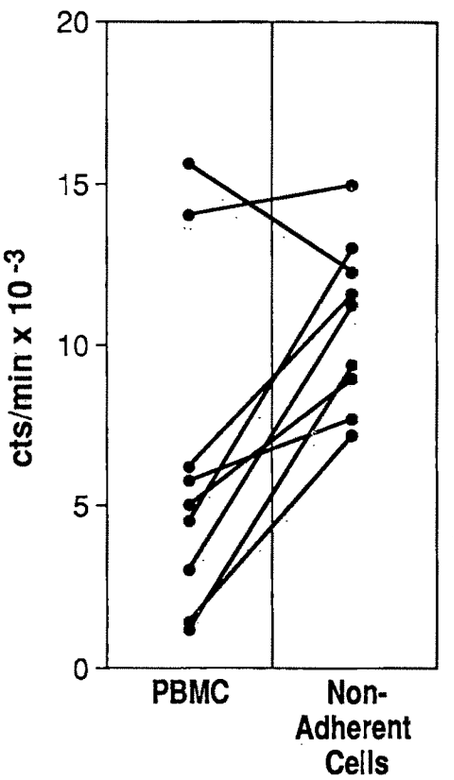

Fig. 1. Effect of monocyte removal on the lymphocyte proliferative response to *C. albicans*. Peripheral blood mononuclear cells *(PBMC)* were isolated from nine persons and monocytes were removed from an aliquot of each by adherence to plastic. Peripheral blood mononuclear cells or nonadherent cells were incubated for 7 days in the presence of *C. albicans* antigens and lymphocyte proliferation was measured.

μg/ml), kanamycin (100 μg/ml), and 10% autologous serum. The final volume was 0.2 ml. Triplicate wells received either no addition, 32 protein nitrogen units/ml of *C. albicans* antigens (Hollister-Stier, Spokane, Wash.), 0.15 ng/ml progesterone with or without *Candida* antigens, or 25 ng/ml progesterone with or without *Candida* antigens. After 6 days in a 37° C, 5% carbon dioxide incubator, tritium-thymidine (0.2 μCi/well) was added. After an additional 18 hours, the cultures were harvested onto glass fiber filters, washed, and incorporated radioactivity was determined.[7] The triplicate determinations were averaged and the mean value is reported. Radioactivity incorporated in the absence of *Candida* antigens or progesterone was subtracted from the experimental values.

Statistics. The relationship between the immune responses of peripheral blood mononuclear cells and nonadherent cells to *Candida* was evaluated by the Spearman rank correlation test.

5	2.9	2.1	74.9

Progesterone was added at 25 ng/ml.

Results

Effect of monocyte removal on the immune response to *Candida*. Lymphocytes from each of the five men and four women proliferated in the presence of *C. albicans* (Fig. 1). The two women in the proliferative phase of their cycles had higher proliferative responses (6140 and 4576 counts per minute) than did the two women from whom samples were obtained during the luteal phase (1406 and 1246 counts per minute). The lymphocyte responses of the men were each at least double the values obtained with lymphocytes from the women in the luteal phase; responses of three of the men were comparable to the results with proliferative phase–derived lymphocytes from the two women.

Except for the one man with the highest recorded level of radioisotope incorporation, monocyte removal led to a marked increase in lymphocyte responsiveness (Fig. 1)

The magnitude of the increased response after monocyte removal was inversely proportional to the initial response to *Candida* ($p < 0.001$) in both men and women (Fig. 2); that is, those persons whose peripheral blood mononuclear cell response to *Candida* was

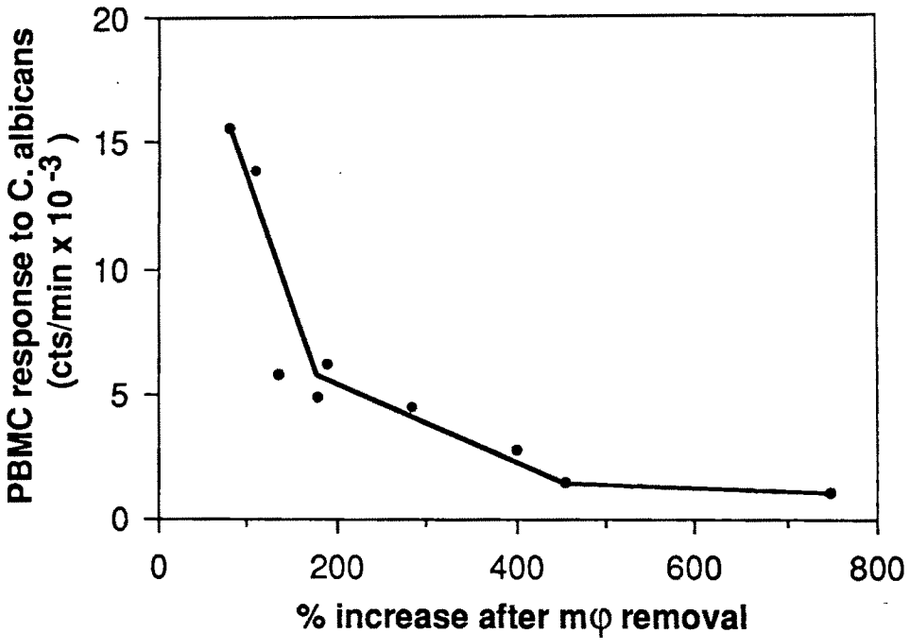

Fig. 2. Relation between the peripheral blood mononuclear cell *(PBMC)* response to *C. albicans* and the percentage increase in lymphocyte response after monocyte removal. The effect of monocyte *(mϕ)* removal on *Candida*-induced tritium-thymidine incorporation by lymphocytes from nine persons was determined.

lowest exhibited the largest increase in lymphocyte proliferation when the monocytes were removed.

Effect of progesterone on the immune response to *Candida*. The effect of exogenous progesterone on the ability of lymphocytes from the five male subjects to respond to *Candida* was evaluated. In the presence of 0.15 ng/ml progesterone, the level found during the proliferative phase of the menstrual cycle,[7] there was a modest stimulation of lymphocyte proliferation in four of the five men (Table I). In marked contrast, increasing the progesterone concentration to the level present during the luteal phase (25 ng/ml) resulted in a modest inhibition of lymphocyte proliferation in all five men (Table II). Comparison of radioisotope incorporation at the two progesterone concentrations makes it apparent that there is an approximate 50% difference in lymphocyte proliferation in the presence of proliferative-phase or luteal-phase levels of this hormone.

Removal of the monocytes completely obviated the ability of 25 ng/ml progesterone to inhibit the immune response to *Candida* in each of the five men (Table III). Lymphocyte proliferation increased to a level 136% ± 32% of that observed by nonadherent cells incubated in the absence of progesterone. Similar to our earlier observations, the percentage increase in radioisotope incorporation after monocyte removal was inversely proportional to the level of incorporation obtained in the presence of monocytes ($p < 0.001$).

Comment

Removal of monocytes from the peripheral blood mononuclear cells of eight of nine men and women enhanced *C. albicans*–induced lymphocyte proliferation. Furthermore, the percentage increase was inversely proportional to the level of proliferation ob-

served in the presence of monocytes. Inhibition of the cellular immune response to *C. albicans* by luteal-phase levels of progesterone appeared to be similarly regulated by monocytes. In the absence of monocytes, progesterone was no longer immunosuppressive and the percentage increase was also inversely proportional to the level of proliferation in the presence of monocytes. Thus individual differences in the ability of monocytes to regulate lymphocyte proliferation is a major determinant of the extent of cell-mediated immune system activation induced by *C. albicans*. Monocyte-dependent variations in the extent of lymphocyte proliferation between persons has been observed previously.[8] Perhaps monocytes from each subject in this study differed in their capacity to differentiate into macrophages, process *Candida* antigens, or present them in association with major histocompatibility class II antigens to T-lymphocytes. Alternatively, quantitative difference in the production of monocyte products such as interleukin-1 or prostaglandin E_2 would also be expected to influence the extent of lymphocyte proliferation. Experiments to differentiate between these possibilities are in progress.

The observation that low levels of progesterone stimulate whereas high levels inhibit lymphocyte proliferation are in agreement with a previous report[9] that showed that low concentrations of progesterone stimulated production of interleukin-1 by monocytes; at higher progesterone levels, interleukin-1 release was significantly decreased. Interleukin-1 is required for the induction of lymphocyte proliferation.[10]

In contrast to the effect of luteal-phase levels of progesterone on *Candida*-induced lymphocyte proliferation, proliferative-phase or luteal-phase levels of estrogen were not inhibitory (data not shown). Thus fluctuations in progesterone levels during the menstrual cycle appear to be responsible for the inhibition of cell-mediated immunity[7] and the onset of *Candida* vaginitis during the luteal phase. Progesterone-induced immune suppression has been observed previously. In two studies[11, 12] progesterone inhibited early events in lymphocyte proliferation, suggestive of an effect on monocytes. In a third study,[13] however, the kinetics of progesterone-induced inhibition suggested a direct effect of the hormone on T-lymphocytes. This study supports the two former studies that indicate the existence of a monocyte-dependent step in progesterone-mediated immunosuppression.

In general, a variety of experimental evidence[1, 4, 14] suggests that the degree of susceptibility of women to contracting a *Candida* vaginal infection may be influenced by alterations in monocyte activity induced by genetic, environmental, and hormonal factors. Identification of highly susceptible women and development of techniques to augment their cellular immune responses to *Candida* may ultimately be beneficial to reduce the frequency of recurrences of *Candida* vaginitis.

Regulation of CA 125 production by amnion and WISH cells in culture

Antonella Barbati, PhD, Lorena Broccucci, PhD, Maurizio M. Anceschi, MD, PhD, and Ermelando V. Cosmi, MD

Perugia, Italy

Amnion and human amnion–derived WISH cells release CA 125 antigen into culture medium. CA 125 output was higher in WISH cells than in amnion cells. In this study we showed that release of the antigen is regulated, with both amnion and WISH cells responding in a similar manner to the tested agents. Release of CA 125 decreased in the presence of dexamethasone (10^{-6} mol/L) or cycloheximide (0.1 μg/ml) and increased when colchicine (0.01 μg/ml) was added to the culture medium. Stimulatory and inhibitory effects were more apparent after 3 days in culture. The precise mechanisms by which some of these agents (colchicine and dexamethasone) affect CA 125 release remain unknown. We propose that amnion and WISH cells in culture represent a useful model to investigate some regulatory aspects of the production of CA 125 in normal tissues. (Am J Obstet Gynecol 1991;164:1355-9.)

Key words: CA 125 release, amnion, WISH cells, colchicine

The cancer antigen CA 125, first found to be elevated in >80% of epithelial ovarian carcinomas[1] and in a minor percentage in a variety of nonmalignant diseases,[2,3] has also been detected in normal biologic fluids such as human milk,[4] cervical mucus,[5] seminal plasma (unpublished data), serum of pregnant women in the first trimester of gestation, and in amniotic fluid.[6,7] Furthermore, CA 125 was detected in fetal müllerian duct derivatives, fallopian tube, endometrium, endocervix, pleura, pericardium,[8] and recently in placental tissues,[6,9,10] suggesting that CA 125 may be a secretory product of many normal human epithelia. In a recent study,[11] we reported that CA 125 was detectable in human amnion cells in primary culture and in their culture medium, in which the antigen accumulated as a function of time.

A poorly investigated aspect is the regulatory pattern of cellular expression of CA 125. In vitro it has been shown that CA 125 expression by ovarian carcinoma cell lines is modulated by certain agents,[12,13] whereas in vivo serum levels of CA 125 seem to respond to hormonal stimulation.[14]

To elucidate some of the mechanisms involved in the regulation of CA 125 expression in vitro, this study was undertaken to evaluate whether CA 125 antigen production or release by amnion and WISH cells, a human amnion–derived cell line that retains some of the characteristics of amnion epithelium,[15,16] is a modulated process.

Material and methods

Cell cultures

Amnion cells. Primary cultures of human amnion cells were prepared from term placentas obtained at the time of elective cesarean section, as previously described.[11] The cells, approximately 40,000 cells/well per 0.2 ml, were seeded in 96 sterile flat-bottom well (0.6 cm diameter) plates (Linbro, Flow Laboratories, Irvine, United Kingdom), and grown in a mixture of Dulbecco's modified Eagle's medium and nutrient mixture F-12 Ham. The cells became confluent within 10 to 14 days. Confluent cultures were used for all experiments, which were conducted with replicates of three wells of amnion cells.

WISH cells. The human amnion–derived WISH cell line (ATCC CCL25) was obtained from the American Type Culture Collection, Rockville, Md. Approximately 20,000 cells/well in 0.2 ml were subcultured in 0.6 cm diameter wells in minimum essential medium with Earle's salts and L-glutamine (2 mmol/L), penicillin (100 U/ml), streptomycin (100 μg/ml), and heat-inactivated newborn calf serum (10% vol/vol) were added. Maintained at 37° C in an atmosphere of air and carbon dioxide (5%), the cells routinely attained confluence within 72 hours.

Treatments. To normalize the difference in growth

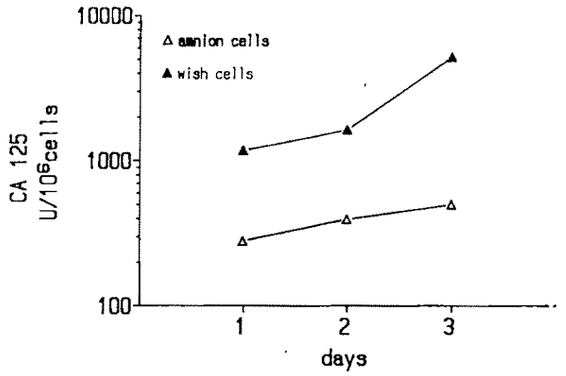

Fig. 1. Comparison of CA 125 accumulation into the medium of amnion and WISH cells in culture as function of time (days post confluence). Each point represents the mean of three replicates from two different experiments. Note logarithmic scale.

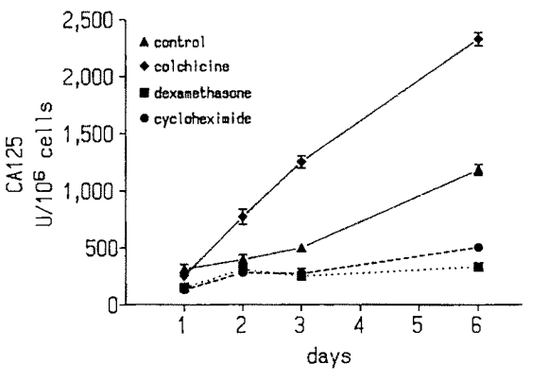

Fig. 2. Effect of colchicine (0.01 μg/ml), dexamethasone (10^{-6} mol/L), cycloheximide (0.1 μg/ml) on CA 125 accumulation into the medium of amnion cells in primary culture. At 3 and 6 days post confluence, difference between control and treatments was statistically significant by analysis of variance ($p < 0.05$). Dexamethasone vs cycloheximide, NS.

rates between control and treated cells, all experiments were conducted with confluent monolayers of amnion or WISH cells (confluence being evaluated by inspection of the culture under inverted microscopy). At confluence (day 0) each well was washed once and fresh medium was added with three replicates for each experimental condition.

CA 125 production was determined after incubation of cells in medium alone (control) and medium with the following substances added: dexamethasone (10^{-6} mol/L), colchicine (0.01 μg/ml), cycloheximide (0.1 μg/ml), actinomycin (0.012 μg/ml) and tunicamycin (1.25 μg/ml), purchased from Sigma Chemical Co., St. Louis. These concentrations were selected because they were the highest that did not affect cell viability, as evaluated by trypan blue exclusion in preliminary experiments.

Collection of samples. The medium was not changed until collection at days 1, 2, 3, and 6 for amnion cells, and at days 1, 2, and 3 for WISH cells. Harvested medium was centrifuged at 3000 *g* for 10 minutes to remove cells and debris and stored at −20° C until assayed.

CA 125 assay. CA 125 was assayed by an immunoradiometric kit (Sorin Biomedica, Saluggia, Italy). Dilutions of samples (1:5 to 1:10) were used for the determination of CA 125 in medium from WISH cells because levels often exceeded 500 U/ml (the highest point of the standard curve). Dilutions were made with minimum essential medium.

Cell count and protein content. To normalize CA 125 data to cell number and cell protein content, cell monolayers were detached at 37° C with a solution of 0.25% trypsin (wt/vol) and 0.02% ethylenediaminetetraacetic acid (EDTA) at the time of medium collection and counted with a hemacytometer chamber. For determination of protein content, the cells were washed once and suspended in sonication buffer (Tris hydrochloride 12 mmol/L, EDTA 10 mmol/L, sodium chloride 100 mmol/L, Triton X-100 0.1%). Cells were then disrupted by sonication (three bursts of 5 seconds each) and protein content was measured with the Bio-rad assay (Bio Rad Laboratory, Muenchen, Federal Republic of Germany).

Statistical analysis. Statistical differences were assessed with the Student *t* test for comparison of CA 125 release by amnion and WISH cells and by one-way analysis of variance for treated and control cells. The experimental conditions were repeated with replicates of three wells for cultures of amnion and WISH cells.

Results

Comparison of CA 125 release by amnion and WISH cells. At 1, 2, and 3 days post confluence, the medium from WISH cells in culture contained a higher amount of CA 125 than did medium from amnion cells with a median value of 1070, 2970, and 5900 U/10^6 cells for WISH cells, respectively, *vs* 270, 390, and 500 U/10^6 cells for amnion cells, respectively (Fig. 1). Both of them continuously produced and released CA 125, as demonstrated by the pattern of accumulation in culture medium. A lag period of about 2 hours occurred to found levels of CA 125 immunologically detectable (data not shown). Amnion and WISH cells maintained in serum-free medium produced less CA 125 than that of cells maintained in medium with serum added (data not shown).

sone or cycloheximide was reduced by about 50% at day 3 post confluence (suppressor index, 50% for dexamethasone; 46% for cycloheximide). In treated cultures at 6 days post confluence, the suppressor index rose to 72% for dexamethasone and 58% for cycloheximide.

By contrast, colchicine acted as an inducer of CA 125 production (stimulator index, 1.5 and 2 at days 3 and 6 post confluence, respectively; Fig. 2).

Total cell number and viability as assessed by trypan blue exclusion was not affected by treatment with the various substances studied (Table I).

When amnion cells were directly seeded in the presence of dexamethasone (10^{-6} mol/L) and CA 125 measured at various periods post confluence, treatment with dexamethasone resulted in an enhanced inhibitory effect (93%) on CA 125 release from day 1 onward (Fig. 3).

Regulation of CA 125 production in WISH cells. The same experiments performed with WISH cells for release of CA 125 indicated a response pattern similar to that of amnion cells. The amount of CA 125 released by WISH cells treated with dexamethasone 10^{-6} mol/L tended to be lower at day 3, although not statistically significant. Cycloheximide significantly inhibited CA 125 production, causing a 33% decrease in basal output (Fig. 4). Incubation of cells in the presence of colchicine induced CA 125 release with levels increasing about sixfold after 3 days in culture (Fig. 5). Exposure to colchicine prevented cell proliferation, which usually occurs in WISH cells even after confluence, so that total cell number, but not viability, was reduced (Table I). Colchicine was effective in the stimulation of CA 125 release by WISH cells in serum-free medium (data not shown). Actinomycin and tunicamycin treatments did not have significant effects on CA 125 production after 3 days. When CA 125 data were normalized to cell protein content, the response pattern was similar to that observed per 10^6 cells.

Comment

In this study we used human amnion cells in primary monolayer culture as a model system for the study of the regulation of CA 125 synthesis in vitro. It was demonstrated that the production of CA 125 was stimulated by colchicine and inhibited by dexamethasone and cycloheximide. Further, CA 125 production by the hu-

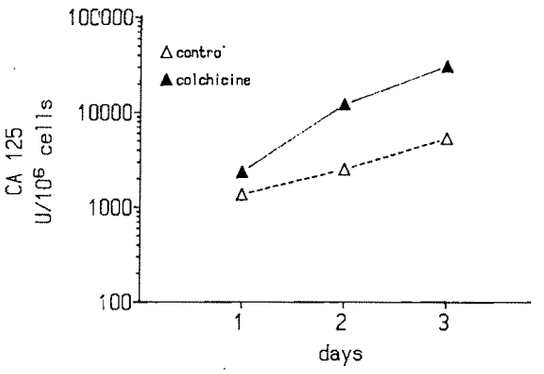

Fig. 5. Effect of colchicine (0.01 μg/ml) *(closed triangles, solid line)* on CA 125 accumulation into culture medium of WISH cells with respect to control *(open triangles, dashed line)* as function of time (days post confluence). Each point represents the mean of replicates of three from four different experiments. Note logarithmic scale.

man amnion–derived WISH cell line was modulated in a manner similar to that observed in primary cultures of human amnion.

In the presence of inhibitors of protein synthesis, production of CA 125 by these cells was inhibited. Cycloheximide, a potent translation inhibitor, reduced CA 125 output from amnion and WISH cells in culture, providing evidence that intact protein synthesis is required for CA 125 release. However, the output of the antigen did not seem to be completely suppressed, suggesting the existence of intracellular stores of the glycoprotein, which continues to be released at a slower rate even in the presence of inhibition of protein synthesis. Although it is not possible to conclude that CA 125 is synthesized again by these cells, the release pattern and inhibition in the presence of cycloheximide is highly suggestive of such a possibility.

Dexamethasone was shown to decrease CA 125 expression more effectively in amnion than in WISH cells in culture. The effect was similar to analogous studies performed on ovarian carcinoma cell lines. It has been reported that OVCA-433 (a human ovarian carcinoma cell line) contains glucocorticoid receptors with high affinity for dexamethasone and that treatment with dexamethasone markedly inhibits (90%) the release and surface density of CA 125 by the same cell line.[12, 17] The higher inhibitory effect of dexamethasone on CA 125 release by OVCA-433, as compared with the results of this study, is probably related to the fact that a longer period of incubation (7 days) was used and dexamethasone was added at the time of cell seeding.

The mechanisms by which dexamethasone depresses CA 125 expression are still unclear. As suggested by Karlan et al.,[12] dexamethasone could directly inhibit the production of CA 125 at the level of protein synthesis, or it could alter the protein conformation or glycosylation states, which would in turn destroy or block the CA 125 determinant. Alternatively, dexamethasone might induce either a protein, which binds to the glycoprotein and blocks the CA 125 determinant, or an enzyme, which specifically destroys or alters the glycoprotein. The reported difference in dexamethasone inhibition of CA 125 between amnion and WISH cells may be because of a different number of receptors for dexamethasone.

After incubation with colchicine, release of CA 125 was markedly induced both in amnion and WISH cells in culture in a time-dependent fashion. The increased CA 125 shedding into culture medium in the presence of colchicine was not associated with increased cell lysis because cell viability in treated and control cultures was not affected with the concentrations of colchicine used in the experiments, as determined by trypan blue exclusion (>90% in both control and treated cells). The effect of colchicine on WISH cells, which unlike amnion cells tend to proliferate even after reaching confluence, seemed to be cytostatic rather than cytolytic.

Colchicine, a known antimitotic drug, is known to bind to tubulin, inducing a conformation change of the protein, which causes an alteration in the assembly of cell microtubules.[18] In unrelated experiments on isolated type II pneumonocytes, colchicine has been shown to stimulate basal secretion of surfactant, which involves microtubular structures.[19, 20] How alteration of cytoskeleton elements might mediate CA 125 production or release remains to be elucidated, although it is tempting to speculate that colchicine acts on secretion rather than on production of the glycoprotein.

Induction of CA 125 in vitro has also been reported in an ovarian carcinoma cell line (HTB-77) treated with interferon-γ, the effect of which was time-dependent and maximal after 3 days in culture.[13] Nonetheless, our study is the first to describe an induction of CA 125 in normal tissue in vitro. Although amnion cells are clearly not neoplastic, their marked proliferation during pregnancy suggests the presence of a common cellular mechanism that regulates antigen production in rapidly proliferating cells.

The involvement of ribonucleic acid synthesis in CA 125 output was studied with actinomycin D, a ribonucleic acid polymerase inhibitor. In this study treatment with actinomycin D for 3 days did not affect significantly CA 125 output in WISH cells. The fact that actinomycin does not interfere with CA 125 accumulation may be consistent with a mechanism in which CA 125 production is regulated at a posttranslational level. Alternatively, the putative messenger ribonucleic acid for the protein may have a long half-life or be particularly stable.

Tunicamycin, an inhibitor of protein glycosylation, did not have any significant effect on CA 125 expres-

sion on WISH cells, suggesting that the antigenic determinant is not affected by inhibition of protein glycosylation.

The findings of this study are several: (1) amnion and WISH cells produce CA 125; (2) the output is higher in WISH cells than in amnion cells; (3) several agents modulate CA 125 release in amnion and WISH cells in a similar manner; (4) CA 125 output is a dynamic and regulated process. On the basis of the findings of this investigation, we propose that amnion cells maintained in monolayer culture represent an appropriate model for the study of the regulation of CA 125 biosynthesis in this tissue. In addition, amnion and WISH cells can be used by many investigators to study specific aspects of the regulation of oncofetal antigens in amnion and in tumor tissues.

Corrections

In the article by Silver et al., entitled "Risk factors for perinatal group B streptococcal disease after amniotic fluid colonization" (Am J Obstet Gynecol 1990;163:19-25), in Table V, on page 22, under *Bacteremia,* for Serotype Ia the mean antibody level of 80.6 was printed with a standard deviation of 55.5. The correct mean is 80.6 but the standard deviation should be omitted.

In the Reply by Johnson and Richards (Am J Obstet Gynecol 1990;163:1364), in line 28, "pH 7.21" should have been "pH 7.12."

LETTERS TO THE EDITORS

Anesthesia and funic acid-base values

To the Editors: I read with great interest the article by Shyken et al. (Shyken JM, Smeltzer JS, Baxi LV, Blakemore KJ, Ambrose SE, Petrie RH. A comparison of the effect of epidural, general, and no anesthesia on funic acid-base values by stage of labor and type of delivery. AM J OBSTET GYNECOL, 1990;163:802-7). Several points regarding their method and results deserve further comment.

First, the authors place considerable emphasis on their finding of significantly lower umbilical arterial and venous partial pressure of oxygen (P_{O_2}) values in the infants who were born during epidural anesthesia versus those born during general anesthesia for cesarean delivery. However, rather than dwelling on the lower P_{O_2} values in the epidural anesthesia group, the authors should have emphasized that the general anesthesia group had *higher* P_{O_2} values, a result that is easily explained by the fact that administration of general anesthesia usually includes 30% to 50% fraction of inspired oxygen (via endotracheal tube and positive-pressure ventilation) after preoxygenation with 100% oxygen.[1] It is unlikely that maternal fraction of inspired oxygen (and thus maternal P_{O_2}—a parameter that is not mentioned by Shyken et al.) was comparable in the general anesthesia group versus epidural anesthesia group during cesarean delivery. Moreover, by what mechanism do the authors propose that epidural anesthesia can lower neonatal P_{O_2} values? Their statement, "Another reason for relative hypoxemia and hypercarbia associated with the use of epidural analgesia is hypotension as a result of sympathetic blockade" is made without reference. The article by Brizgys et al.[2] (which is referred to by the authors) found only a slightly lower pH (7.31 vs 7.33) when hypotension occurred during cesarean delivery; P_{O_2} and partial pressure of carbon dioxide values were unaffected.

Second, the acid-base values of the neonates who were born by vaginal delivery are claimed by the authors to be attributable to the longer labors of these women. Considerable controversy exists regarding the acid-base sequelae of long labors.[3] This retrospective study is subject to all of the selection biases that flaw the numerous other retrospective studies that correlate the length of labor with the use of epidural anesthesia. One wonders if the results of Shyken et al. would have been different if all of the patients in the vaginal delivery group had been randomized to receive either epidural anesthesia or no anesthesia during labor? As stated in a recent letter to this JOURNAL,[4] the time has come for a prospective, randomized trial of epidural anesthesia versus no epidural anesthesia during labor. (However, it would appear difficult to ethically design and execute such a study.)

Finally, and most important, is that the study by Shyken et al. makes no mention of maternal risks of general anesthesia versus epidural anesthesia. A recent review discusses the inherent risks of general anesthesia for the parturient, in which all anesthetic-related deaths in North Carolina over a 40-year period were attributable to complications from general anesthesia.[5] Another similar review in Massachusetts found that the vast majority of anesthetic-related deaths over a 30-year period were related to general anesthesia, and all such deaths over the last decade were a result of general anesthetic complications.[6] At our institution, we perform more than 2500 cesarean deliveries per year; our rate of use of general anesthesia has been steadily declining over the last two decades and is currently about 8%. We are proud of this accomplishment. Shyken concludes by stating that his results are "unlikely . . . to be clinically important for the term fetus with a normal electronic monitor pattern." We quite agree, and therefore other factors must be considered when an anesthetic technique is chosen. If the data by Shyken et al. are ever used to discourage a woman from having epidural anesthesia during labor or conversely, to encourage the use of general anesthesia for cesarean delivery, then a great disservice will have been done, not only to the obstetric and anesthetic communities, but especially to the women and infants who seek our expertise in obtaining safe and comfortable childbirth.

Reply

To the Editors: We appreciate the interest expressed by Dr. Camann regarding our article. It is generally accepted that a difference in fetal partial pressure of oxygen may be based on maternal administration of oxygen. The hypothesis that preoxygenation alone explains the higher partial pressure of oxygen in the general anesthesia group can be tested by factor analysis for the independent effects of respiratory function,

metabolic function, and oxygenation. Such analyses of our data reveal that respiratory function is higher with vaginal delivery versus cesarean section and with no anesthesia versus epidural anesthesia and that with cesarean, there is no difference between epidural and general anesthesia. Metabolic differences are small between groups, but reserve was lower with labor compared with no labor and with no anesthesia compared with epidural anesthesia. Oxygenation was higher with general anesthesia versus epidural anesthesia, but only during labor.

A decrease in mean maternal arterial blood pressure during conduction anesthesia reduces uterine blood flow proportionately[1, 2] and has the potential for fetal compromise. Our study demonstrated no significant relationship between hypotension and acid-base parameters.

In spite of the contention that controversy exists regarding the acid-base sequelae of length of labor,[3, 4] our data demonstrate longer durations of stage I and stage II in women who have epidural analgesia compared with women who do not have it. This protraction is independent of parity and explains the decreases in pH and venous partial pressure of oxygen in women who delivered vaginally with epidural anesthesia. It is possible that women who had "more difficult labors" were selected for epidural anesthesia by their physicians. We understand the limitations of any retrospective study. However, a prospective, randomized trial does not appear to be forthcoming.

Last, the data that are presented in our article are not intended to disparage the use of epidural analgesia-anesthesia for labor or cesarean section; to do so would represent gross overinterpretation of our results. The intent was not to compare maternal morbidity with general or epidural anesthesia. Rather, the purpose, as stated, was to investigate the premise that epidural analgesia, when compared with no anesthesia or general anesthesia, was advantageous *to the fetus*. In fact, we found no such advantage in the healthy fetus, born of a normal pregnancy at the end of labor, by cesarean section during labor, or by elective cesarean section. We did not generalize to other populations or otherwise indict epidural anesthesia. The highly important maternal considerations of safety and comfort are entirely different issues that are intentionally not addressed in this study.

Embryoscopy: Old technique new for the 1990s?

To the Editors: With great interest I read the article by Cullen et al. (Cullen MT, Reece EA, Whetham J, Hobbins JC. Embryoscopy: Description and utility of a new technique. AM J OBSTET GYNECOL 1990;162:82-6). The authors did not point out that all the previous authors cited in the references incorrectly believed the chorionic membrane has transparent areas through which visualization of the embryo is possible. They did not understand that only chorion perforation makes embryo observation possible and therefore they did not continue with their investigations.

My experience in embryoscopy is similar to that of Cullen et al. and I can confirm that only perforation of the chorion allows the visualization of the embryo. In 1984 I investigated the possibility of whole embryo visualization in the first series of 100 cases between 8 and 13 weeks' gestation. The study was conducted without ultrasonographic guidance immediately before suction curettage in women undergoing voluntary abortion. I used an endoscope with an outer diameter of 4 mm and a length of 30 cm. In 75% of the cases visualization of the whole embryo was achieved. In two patients a diagnostic attempt to continue the pregnancies was successfully performed. The pregnancies continued uneventfully and reached term. The children are now 6 and 5 years old, respectively.[1]

In 1985 I performed embryoscopy in another series of 62 cases between 7 and 12 weeks' gestation. I used the optic of the Chorionscope (length, 30 cm; outer diameter, 2.7 mm; angle, 70 degrees) (Richard Wolf,

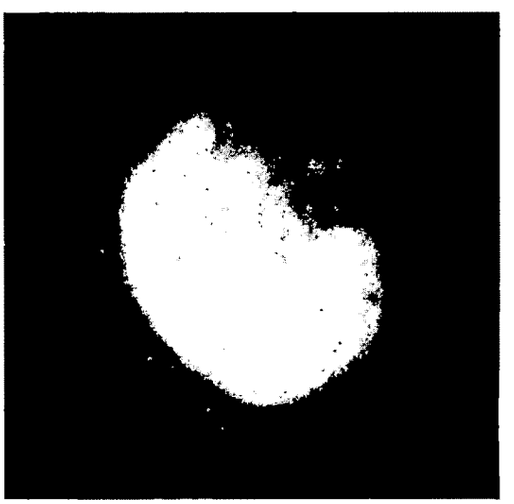

Fig. 1. Ultrasonographic diagnosis at 82 days' gestation, blighted ovum. Embryoscopy, abnormal residual embryo.

Knittlingen, Federal Republic of Germany).[2] The results were similar to the first series. I never observed complications such as rupture of the membrane, uterine perforation, or postoperative infection. However, I abandoned this endoscopic technique in viable pregnancies because of two main reasons: (1) at that time introduction of vaginal ultrasonography[3] convinced me that the same results of embryoscopy could be obtained by this noninvasive method in the first trimester of pregnancy, and (2) the extraembryonic cavities provide the surroundings in which the actual embryonic body starts its development and the consequences of chorion perforation are not known.

This personal experience leads me to disagree with the belief of Cullen et al. that direct access to the embryo by embryoscopy opens a new frontier into prenatal diagnosis and treatment, at least in viable pregnancies. However, embryoscopy could be applied as an investigative method in pathologic pregnancies (e.g., blighted ovum). I believe that in such cases our knowledge could be enhanced by the use of this technique (Fig. 1).

Reply

To the Editors: Dr. Ghirardini states that we neglected to mention that previous authors had suggested that one could adequately visualize the embryo through the chorion. Our work clearly shows that one must penetrate the chorion to properly examine the embryo through the transparent amnion. Frankly, we did not think the above concept was worth debating.

We apologize for not referencing Dr. Ghirardini's experience, but we were not privy to information aired at the Naples conference in 1984. The other references he cited pertained to trophohlast sampling. In any case, we are delighted to hear about his experience with endoscopy.

We share Dr. Ghirardini's sentiments about the lack of potential for embryoscopy as a diagnostic tool for visualization of the embryo in continuing pregnancy.[1] However, we have found embryoscopy to be extremely useful in the validation of ultrasonographic findings before termination of pregnancy, evaluation of failed pregnancies, and we feel very strongly about its potential to gain access to the embryonic circulations for purposes of therapy.

Dr. Ghirardini's data would tend to support the safety and potential utility of this procedure.

Fetal-neonatal thrombocytopenia: Mode of delivery?

To the Editors: In their retrospective review of neonatal thrombocytopenia (Burrows RF, Kelton JG. Low fetal risks in pregnancies associated with idiopathic thrombocytopenic purpura. Am J Obstet Gynecol 1990;163:1147-50) Burrows and Kelton concluded that the relative lack of poor neonatal outcomes in cases of maternal idiopathic thrombocytopenic purpura prompted comment on obstetric management, including route of delivery. They suggest that because so many infants are unaffected by this disease that cesarean delivery cannot be justified in every case.

I have two problems with their publication. First, one must question their study group inasmuch as they did not require direct nor indirect antibody presence for a diagnosis of maternal disease. In fact, of the 46 mothers tested only eight had elevated platelet-associated immunoglobulin G. Is this the current standard in the field of hematology with regard to the diagnosis of idiopathic thrombocytopenic purpura? Second, the central question still remains unanswered: given a fetus with low platelet count as a result of maternally derived antibody, is abdominal delivery protective against fetal-neonatal hemorrhage?[1] Until this question is answered we will have to continue to rely on data such as published here, although it only indirectly touches on the basic problem.

Donald L. Levy, MD
Division of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, Eastern Virginia Medical School, 825 Fairfax Ave., Norfolk, VA 23507

REFERENCE

1. Levy DL. Fetal-neonatal involvement in maternal autoimmune disease. Obstet Gynecol Surv 1982;37:122-7.

Reply

To the Editors: We thank Dr. Levy for his interest in our article. Dr. Levy raises two important points: the first is whether our patients had idiopathic thrombocytopenic purpura or whether they had a less severe illness, which would account for the good infant outcome. The second is whether the type of delivery should be an important consideration for infants of mothers with idiopathic thrombocytopenic purpura.

We are confident that our study group is representative of typical patients with idiopathic thrombocytopenic purpura. We were careful to exclude those patients with incidental thrombocytopenia of pregnancy because this condition does not carry risk for the mother or her fetus and by including such patients one would have an inaccurately optimistic picture of idiopathic thrombocytopenic purpura. Indeed, if anything, our patient population could be skewed toward a worst-case bias because we serve as a referral center for patients with idiopathic thrombocytopenic purpura. Idiopathic thrombocytopenic purpura is a diagnosis of exclusion and the measurement of platelet-associated immunoglobulin G is neither sufficiently sensitive nor specific to be used as a diagnostic test for the disorder. Furthermore, the likelihood of a positive result is directly related to the severity of the thrombocytopenia and consequently mothers with moderately severe thrombocytopenia who have ITP often have normal platelet-associated immunoglobulin G. If our patients are a true and representative example of typical pregnant patients with idiopathic thrombocytopenic purpura, what is the explanation for the relatively benign outcome our patients had compared with previous reports in the literature? We believe that the major factor is that our focus was on the fetal cord platelet count, the parameter of greatest interest to obstetricians when attempting to estimate the risk of bleeding in utero or at the time of delivery. Previous studies have focused on the platelet nadir, which we have shown typically occurs several days after delivery.

The real question is not whether abdominal delivery is protective but whether vaginal birth is harmful in infants of mothers having idiopathic thrombocytopenic purpura. Only when this risk is measured can the benefits of an intervention (cesarean section) be defined. Our contention is that, given the low risk of severe neonatal thrombocytopenia at the time of birth ($<20 \times 10^9$/L), we question whether routine cesarean section can ever be justified in pregnant patients with idiopathic thrombocytopenic purpura.

This is not to say that idiopathic thrombocytopenic purpura in pregnancy is not an important disorder; rather the greatest risk for the infant occurs several days after delivery and consequently the focus of concern shifts from the obstetrician to the pediatrician.

Parvovirus transmission concerns

To the Editors: The recent article by Rodis et al. (Rodis JF, Quinn DL, Gary GW Jr, et al. Management and outcomes of pregnancies complicated by human B19 parvovirus infection: a prospective study. Am J Obstet Gynecol 1990;163:1168-71) proposes a management protocol for evaluation of pregnant women exposed to B19 parvovirus in pregnancy. The initial step in this protocol is to determine the susceptibility of exposed women by performing serologic testing for the presence of B19-specific immunoglobulins. It is important to recognize that infected persons typically incubate the virus for approximately 1 week (usual range, 4 to 14 days) before becoming symptomatic and are likely to be contagious during this period without symptoms.[1] Occasionally, the contagious period may last as long as 20 days after exposure.[2] A helpful rule is that once the characteristic "slapped cheek" facial rash appears, there will be little or no virus remaining in respiratory secretions and therefore the person is extremely unlikely to be contagious. The incubation and transmission characteristics of B19 parvovirus raise concerns that inadvertent iatrogenic exposure to susceptible health care workers and obstetric patients may occur when an exposed patient is seen for serologic studies, genetic counseling, and ultrasonography. Caution must be exercised in these settings.

The Pregnancy Healthline at Pennsylvania Hospital has used a B19 parvovirus in pregnancy protocol that is remarkably similar to that used by Rodis et al. with the additional caution that serologic testing be performed at a facility that does not care for pregnant women or at a time that minimizes the risk of exposure of other pregnant women to a potentially infectious person. In addition, it is recommended that health care workers (physicians, sonographers, nurses, genetic counselors, phlebotomists, and clerical staff) who are likely to be exposed to these potentially infectious women should undergo serologic testing to determine their B19 parvovirus immunologic status.

B19 parvovirus may cause nonimmune hydrops, which can be successfully treated in utero.[3] This knowledge has led to pregnancy surveillance protocols that are designed to detect fetal compromise before deterioration is irreversible. In the course of using these protocols, it is important to avoid jeopardizing other pregnant women and minimize the further risk of transmission of B19 parvovirus.

Alan E. Donnenfeld, MD, and
Betsy Schick-Boschetto, RNC, MSN

Section of Genetics, Department of Obstetrics and Gynecology, Pennsylvania Hospital, Eighth and Spruce Streets, Philadelphia, PA 19107

Reply

To the Editors: We appreciate the comments by Dr. Donnenfeld and Ms. Schick-Boschetto. We agree with them that iatrogenic parvovirus exposure of susceptible health care workers and obstetrics patients is to be avoided. We also agree that serologic testing for pregnant health care workers may be helpful so that those who are susceptible to infection can avoid exposure when possible, although there are no data to suggest that this is effective. Thus common sense should be used in screening patients for parvovirus infection just

as in any other potentially serious viral infection (e.g., varicella).

However, we recommend that caution be exercised when referring patients to commercial laboratories for parvovirus testing because during our outbreak both false-positive and false-negative results occurred when private laboratories were used. We suggest that whereas the blood sample may be obtained at any location, the specimen should be analyzed at a reference laboratory where quality control can be assured, such as the viral laboratory at the Centers for Disease Control or laboratories of the State Health Departments in the respective states.

Computerized digital colposcopy

To the Editors: In a previous article, Crisp et al. emphasized the technology and possible applications of a computerized digital imaging colposcope (Crisp WE, Craine BL, Craine EA. The computerized digital imaging colposcope: Future directions. AM J OBSTET GYNECOL 1990;162:1491-8). For more than a year, we have had a positive experience with the same DENCOL 2100 computer system. Whereas standard colposcopy is a subjective diagnostic modality that depends on the experience and visual perception of individual colposcopists, computerized digital colposcopy has the capacity to objectively quantitate and analyze colposcopically visualized lesions. The system in its current form though has some limitations. The software needs to be refined. The menu requires some modifications, and color should be introduced to the black-and-white image to enhance the research and clinical potential of this promising technology.

The use of cervicography has been controversial.[1-3] Unlike cervicography, computerized digital colposcopy permits image processing and analysis, contrast and edge enhancement, computer-assisted quantification of lesions, and the detection of subtle changes. Colposcopic images can be improved with digital filters and stored. Image processing accentuates differences in cervical morphology and allows for the enhancement of capillary patterns, thereby emphasizing features of the cervix that might otherwise be missed. Serial measurements can be obtained to objectively evaluate progression-regression of cervical lesions. This computer-assisted quantitative-qualitative approach can lead to a more accurate and uniform appraisal of lesions visualized by colposcopy. It may improve our understanding of the natural history of cervical dysplasia and human papillomavirus infection of the genital tract.

Computerized digital colposcopy can be useful in the conservative management of patients with low-grade cervical dysplasia as well as in monitoring pregnant patients with abnormal cervical smears. Sequential computerized image analysis provides objective information as to whether a lesion is progressing, regressing, or stable in size. This may obviate the need for unnecessary active intervention in some cases. A study to evaluate the role of computerized digital colposcopy in the conservative management of low-grade cervical dysplasia is under way in our unit.

3. Spitzer M, Krumholz BA, Chernys AE, et al. Comparative utility of repeat Papanicolaou smears, cervicography, and colposcopy in the evaluation of atypical Papanicolaou smears. Obstet Gynecol 1987;69:731-5.

Reply

To the Editors: We are pleased to see comments by Drs. Mikhail and Romney that confirm many of the advantages we have previously discussed that can be realized by digital imaging colposcopy. With regard to improvements to the software, we note that Western Research Company, Inc. (Tucson, Ariz.), the originator of the digital imaging colposcopy system and software package, has continued to upgrade the software.[1] Changes suggested by Dr. Romney and others in private communications have been implemented and upgrades are available. This software package is continually evolving and Western Research Company anticipates offering a three-dimensional imaging version in the future.

We point out that this work has been supported by several research grants from the National Institutes of Health to one of us (B.L.C.). As a result, much of the development cost has been paid, allowing the provision to interested researchers or clinicians of a good digital imaging system for less than $6000, contrary to the figure mentioned in the comments on the article.

Comments with regard to color are of particular interest to us inasmuch as this is a very complex and poorly understood issue. Some of the adverse aspects of currently available color imaging systems for colposcopy have been addressed by Craine et al.[2] We have continued this research and have serious concerns about medical liability associated with some ill-conceived color systems, particularly as they relate to issues of spatial resolution and detection of high-frequency features in the resultant images. We have under way a research project for evaluation of specific color system parameters and will publish the results of that work when it is complete. In the meantime we will be happy to discuss the issues directly with interested parties.

We do see considerable potential for the use of color images in colposcopy, where the images have been obtained by use of specific color filters.[3] Again, however, we have determined that there are esoteric issues related to the convolution of detector response and broad-band optical filter characteristics, the understanding of which is critical to the limitation of liability. This liability potentially arises from the application of an incorrectly characterized system in which informa-

tion conveyed by the system is actually different from that the physician believes he is receiving. Publication on this subject is in preparation.

Questions about prophylactic intrapartum amnioinfusion

To the Editors: I read the article by Strong et al. (Strong TH Jr, Hetzler G, Sarno AP, Paul RH. Prophylactic intrapartum amnioinfusion: A randomized clinical trial. Am J Obstet Gynecol 1990;162:1370-5) with great interest and respect. Because we at Portsmouth Naval Hospital are still involved in an ongoing clinical trial to assess the efficacy of prophylactic amnioinfusion, I have several questions.

1. What ultrasonographic biometric measurements did you use to derive the estimated fetal birth weight? Was it done during labor? What was the mean percentage error of your estimated fetal weight? How many of the patients who were excluded solely on the basis of the estimated birth weight had birth weight >2500 gm? Was the birth weight of all the fetuses in the amnioinfusion and control groups >2500 gm? How would you manage a fetus with estimated birth weight <2500 gm and amniotic fluid index ≤5.0 cm?

2. Why warm the normal saline solution to 37° C before amnioinfusion? Miyazaki and Taylor[1] in the first known clinical trial of transcervical amnioinfusion stated that the "blood warmer . . . proved to be unnecessary as long as the infusion rate was limited to 10 to 15 ml per minute." Moreover, Miyazaki and Nevarez[2] in their randomized prospective study of amnioinfusion, had the "normal saline solution at room temperature." By advocating the use of normal saline solution warmed to 37° C aren't we adding an additional step that has not been shown to be necessary?

3. What was the mean (±SD) amniotic fluid index after amnioinfusion? Who performed the hourly amniotic fluid index—the same person or different people? Moore and Cayle have shown that the interobserver error for measurement of amniotic fluid index is 7%, whereas the intraobserver error is 3%. And if the amniotic fluid volume is <10 cm the error may be as high as 20%. Therefore it seems that to minimize error of hourly measurement of amniotic fluid index, the same person should take the measurements. Most important, do you recommend that an hourly amniotic fluid index be obtained during the first and second stage of labor if prophylactic amnioinfusion is used among patients with amniotic fluid index ≤5.0 cm?

4. How was fetal distress defined? Is it if there is no fetal heart rate acceleration with scalp or acoustic stimulation or if the scalp pH is <7.20? Was the same criterion of fetal distress used when performing emergency cesarean section as when doing forceps delivery? If not, then the conclusion that amnioinfusion significantly decreased "operative delivery for fetal distress" could probably more precisely read amnioinfusion significantly decreased the need to intervene with forceps for fetal distress. Were any of the authors involved with the decision to intervene because of fetal distress?

5. Although the umbilical arterial blood pH of the amnioinfusion group (7.29 ± 0.03) was "significantly higher than that of the control group (7.23 + 0.09)" what is the clinical significance of this observation? Isn't the critical question with umbilical arterial blood gases whether the neonate is acidotic, and if so, is it respiratory or metabolic acidosis?

6. Rutherford et al.[3] showed that the incidence of low 5-minute Apgar scores among fetuses with amniotic fluid index ≤5.0 cm was 11% but none of the 30 patients in the control group with amniotic fluid index ≤5.0 cm had a low Apgar score at 5 minutes. How do you account for this?

These questions by no means are supposed to distract from a well-designed and well-executed study.

Suneet P. Chauhan, MD

3. Rutherford SE, Phelan JP, Smith CV, et al. The four-quadrant assessment of amniotic fluid volume: an adjunct to antepartum fetal heart rate testing. Obstet Gynecol 1987;70:353-6.

Reply

To the Editors: 1. The fetal head and abdominal circumferences were used to estimate fetal weights. All measurements were done in the latent phase of labor. None of the controls and only one in the study group had birth weights <2500 gm (2460 gm). Whereas no study has addressed prophylactic amnioinfusion for growth-retarded fetuses, in the setting of a reassuring fetal heart rate tracing, prophylactic amnioinfusion may not be unreasonable.

2. Our infusion rate was approximately 20 ml/min, thereby exceeding the "15 ml rule." When the am-

nioinfusate is held 4 feet above the infusion catheter tip, as it is during most amnioinfusion procedures, the rate of infusion will approach 20 ml/min.[1] Therefore many women who receive gravity-flow amnioinfusion may be at risk if room-temperature saline solution is used. Moreover, if amnioinfusion is reserved until variable decelerations occur, the fluid should be infused relatively rapidly. If the amnioinfusate is less than 3 feet above the catheter tip, the rate of amnioinfusion may be too slow to have utility.

3. The mean amniotic fluid index after amnioinfusion was 9.8 ± 2.9 cm (SD). As was stated in the article, only two investigators performed amniotic fluid index assessments. For any given subject, a single investigator performed all amniotic fluid index assessments. The majority (87%) who received prophylactic amnioinfusion maintained amniotic fluid index values above 8 cm for the duration of labor without requiring another amnioinfusion procedure. To reiterate our recommendations, hourly amniotic fluid index assessments after amnioinfusion are probably not necessary.

4. Fetal distress was generally defined as a decelerative fetal heart rate pattern with nonreactivity-decreased fetal heart rate variability that was not responsive to scalp or acoustic stimulation, or outright fetal bradycardia. The same criteria were used for both cesarean and forceps deliveries. As stipulated in the article, none of the authors was involved in the clinical management of any of the subjects.

5. Whereas there was a statistically significant difference in the pH values between the two groups, this difference does not appear to be clinically significant. However, as mentioned in the article, 30% in the noninfused group had pH values <7.20. Of these, 80% were consistent with metabolic acidosis.

6. The difference in the incidence of low 5-minute Apgar scores may be a reflection of the fact that the amniotic fluid index assessments performed by Rutherford were performed during the antepartum period, whereas those done in our study occurred during labor. Sarno et al.[2] assessed amniotic fluid index values early in the intrapartum period and found an incidence of low 5-minute Apgar scores, which was in agreement with that found in our control population.

Panty hose–pants disease

To the Editors: Drs. Bergeron, Ferenczy, and Richart reported on the potential of self-contamination of HPV infections by underwear (Bergeron C, Ferenczy A, Richart R. Underwear: Contamination by human papillomavirus. AM J OBSTET GYNECOL 1990;162:25-9). At a recent lecture on the use of interferon in cases of genital papillomavirus (condyloma acuminatum), I commented that I had successfully used podophyllum resin, electrosurgery, cryosurgery, and autogenous vaccine. However, the most successful and simple treatment occurred about 7 years ago.

A patient in early pregnancy was seen with massive condylomata that encompassed the entire vulva and anal region. Simply, I told the patient to remove her panties and go without them, to wear only skirts or dresses during her entire pregnancy, and to insert one fourth applicator of sulfa cream vaginally every night. Much to my amazement the condylomata completely disappeared within 3 months. It remained clear throughout that pregnancy and delivery and a subsequent pregnancy. With only one case, I could not submit this for publication.

I believe that there is a panty hose–pants disease. Condyloma, *Monilia, Gardnerella,* and *Trichomonas* are involved. These diseases could have been instituted or aggravated with the advent of panty hose, jeans, sweat pants, and most recently leotards and aerobic suits. Recent published articles appear to concur. It is my opinion that we are seeing more of these infections because of the nonbreathable, tight nylon undergarments. I cannot recall seeing many of the mentioned infections in the late 1940s and early 1950s when loose panties (similar to boxer shorts) were commonly worn. It is conceivable that vulvovaginitis is not prevalent in those countries where women wear long dresses and loose undergarments.

Recently I have been advising those patients with recurring vulvovaginitis who insist on wearing panty hose to cut out the crotch or preferably wear loose cotton panties or no panties at all under a long dress. This would permit better air circulation to the anovulvar region, and has proved to be successful in minimizing recurrences.

This approach is old-fashioned common sense medicine to which I had been exposed, having obtained my MD degree in 1941 and completed my formal obstetrics and gynecology training in 1948. I hope that this might stimulate those in the research environment to do further research on the vulvovaginal infections.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1991 issues from the Publisher, at a cost of $61.00 for domestic, $88.27 for Canada, and $84.00 for international for Vol. 164 (January-June) and Vol. 165 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

OB/GYN PARTNERSHIP OPPORTUNITY

Obstetrician/Gynecologist needed to join with a two-physician practice that is starting on the campus of ALBERT EINSTEIN MEDICAL CENTER. A new $6 million labor and delivery suite currently is under construction. A brand new fully-equipped office space is available. The two physicians you will be joining are clinically outstanding and have an established referral base.

Located in the northern part of Philadelphia, you are offered the challenges of a 600-Bed, Level III teaching Hospital that is centrally located to nearby cultural and recreational areas.

We offer a competitive compensation and benefit package. If you like to teach, that opportunity is available through the Albert Einstein Ob/Gyn Residency program.

Applicants must be Board-Certified or an active candidate for board certification.

Send Curriculum Vitae to:

Sze-ya Yeh, M.D.
Chairman, Dept. of Ob/Gyn
Suite 410, Klein Bldg.
Albert Einstein Medical Center
5401 Old York Rd.
Philadelphia, Pennsylvania, 19141
(215) 456-6993

PENNSYLVANIA HOSPITAL MATERNAL-FETAL MEDICINE FELLOWSHIP

The accredited fellowship in Maternal-Fetal Medicine of the Pennsylvania Hospital is seeking applicants for a position as a first year fellow beginning July 1992. The fellowship is a 2 year clinical and research-oriented program. Clinical services are based at Pennsylvania Hospital, a Level III referral center with a staff of 8 perinatologists who operate a large network of antenatal testing units, including genetics services and invasive ultrasonography. The position includes an academic appointment in Obstetrics and Gynecology at the University of Pennsylvania. Applicants must have completed an approved 4 year residency program in Obstetrics and Gynecology. For more information, please write to:

Stuart Weiner, M.D.
Section Chief,
Maternal-Fetal Medicine
Department of OB/GYN
Pennsylvania Hospital
8th & Spruce Streets
Philadelphia, PA 19107

Deadline for applications is **June 17, 1991.**

Pennsylvania Hospital is an affiliate of The University of Pennsylvania and is an affirmative action/equal opportunity employer.

NORTHERN CALIFORNIA

The Permanente Medical Group, a growing multispecialty group, is recruiting physicians in a variety of specialties for positions throughout our beautiful Northern California region: the San Francisco Bay Area, Sacramento and the Central Valley.

Obstetrician/Gynecologist

BC/BE Obstetrician/Gynecologist sought to join small congenial clinic setting within established pre-paid multispecialty group. Practice consists of general obstetrics and gynecology, high risk obstetrics and infertility. Expertise in colposcopy, laparoscopy, hysteroscopy and laser are welcomed. Association with resident staff and teaching opportunities available.

Kaiser Permanente offers competitive salaries and excellent benefits including full coverage malpractice insurance, medical, dental and group life insurance, vacation, educational leave and an excellent retirement program.

For more information, send CV to: Victor David, M.D., Chief, Obstetrics and Gynecology, The Permanente Medical Group, 901 Nevin Avenue, Richmond, CA 94801. EOE

KAISER PERMANENTE
Good People. Good Medicine.

BC/BE OB/GYN

BC/BE OB/GYN for Community Health Center in Tampa Bay, FL. Multi-Specialty Practice offers fixed schedule in modern facility, Midwives, excellent support staff and on-site auxiliary services. Medical School/ Teaching Hospital affiliation.

PELVIC SURGERY FELLOWSHIP

The Department of Obstetrics and Gynecology of S.U.N.Y., Health Science Center at Syracuse is offering a one-year fellowship in Pelvic Surgery for qualified candidates.

The Fellowship will include comprehensive training in benign and malignant pelvic surgery, infertility surgery, laser surgery (abdominal, endoscopic and external genitalia), female urology and endoscopy (laparoscopy, hysteroscopy and colposcopy). The program is designed to provide clinical experience and expertise in gynecologic surgery. Research opportunities are available.

Positions are available beginning July 1, 1991.

Qualifications include ABOG eligible/certified status and eligibility for full NY State licensure.

Requests for applications can be sent to:

Michael S. Baggish, M.D.
Professor and Chairman
Department of OB/GYN
S.U.N.Y., Health Science Center
736 Irving Avenue
Suite 308 West Tower
Syracuse, NY 13210

SUNY, Health Science Center is an AA/EEO Employer

GYNECOLOGIST

Gynecologist needed to fill a staff position in a 57-bed Army Community Hospital located near the beautiful Williamsburg / Hampton Roads Virginia area. Practice gynecology only in an outpatient setting with a qualified paraprofessional staff and access to modern O.R. suites. Excellent retirement benefits with no malpractice insurance requirement. E.E.O.

Interested applicants should address inquires to:

Commander
McDonald Army Community Hospital
ATTN: LTC Anderson
Fort Eustis, VA 23604-5548
or call (804) 878-5250/3600

A full-time position is available in the Department of Obstetrics and Gynecology, University of California, Davis, Medical Center, Sacramento. Applicants should be Board eligible or certified in Obstetrics and Gynecology. Applicants must possess or be eligible for medical licensure in the State of California. Applicants must demonstrate experience and competence in teaching effectiveness and research related activities or potential for such activities. Special interest in the area of urogynecology, adolescent OB/GYN or sexual dysfunction is desired.

Responsibilities of this position include inpatient and outpatient case management, participation in teaching activities with residents, interns and medical students, development and/or participation in research activities and involvement in University and Hospital committees.

Send curriculum vitae and five references to:

R. Jeffrey Chang, M.D.
Chairman, Department of Obstetrics and Gynecology
University of California, Davis, Medical Center
1621 Alhambra Boulevard, Suite 2500
Sacramento, California 95816

The final date for receipt of applications is **June 1, 1991.**

The University of California, Davis is an equal opportunity, affirmative action employer.

FACULTY & FELLOWSHIP
POSITIONS AVAILABLE IMMEDIATELY
Gynecological Oncologist
General Gynecologist/Obstetrician
Fellowship in Pelvic Surgery

The Department of Gynecology and Obstetrics at the University of Kansas in Kansas City is expanding its full-time academic faculty from 12 positions to 14. Faculty applicants will participate in clinical practice activities and medical education in a 12 position residency program. Clinical and/or basic research opportunities are available and encouraged. An opportunity for creative motivated individuals. Financial remuneration and incentives are commensurate with experience, credentials and rank. BC or BE. Position open until filled. Fellowship position, in the Gynecologic Oncology Division, is a 12 month program of post-residency training in advanced pelvic surgery. Areas of interest are oncologic procedures, pelvic reconstruction, incontinence surgery and pelviscopy. Please send Curriculum Vitae to:

John W. Calkins, M.D., Interim Chairman
Department of Gynecology and Obstetrics
KUMC, 39th & Rainbow
Kansas City, Kansas, 66103
(913) 588-6236

EXPLORE
The Kaiser Permanente Perspective

The Ohio Permanente Medical Group is part of the largest and most experienced prepaid managed care provider in America. Our 230-physician group has exceptional opportunities for board certified/eligible physicians in:

OBSTETRICS & GYNECOLOGY

- attractive call schedule
- excellent compensation
- family health, optical, dental and prescription coverage
- disability income protection
- paid life insurance & retirement plans
- relocation assistance
- paid vacation
- shareholder status & profit sharing
- education stipend & leave
- teaching affiliation
- paid malpractice insurance...

Then, there is our ideal location in northeast Ohio—a thriving major metro area with an excellent housing climate, acclaimed symphony, ballet and theatre, Great Lakes recreation, major league sports, and much more. For consideration please direct your resume to: **Ronald G. Potts, M.D., Medical Director, Ohio Permanente Medical Group, Inc., Dept. HROB, 1300 E. 9th St., Suite 1100, Cleveland, OH 44114. Or call 1-800-837-OPMG or 216/623-8770.** eoe

CHIEF OF PERINATOLOGY

West Virginia University School of Medicine seeks a board certified perinatologist to establish and direct a program of regional perinatal care. Successful candidate will hold faculty rank at West Virginia University based on qualifications. The Medical School and Department of Obstetrics and Gynecology are committed to supporting the development of a program with innovative approaches to the improvement of regional perinatal health in West Virginia. The position includes support for (recruitment of) additional personnel and research. The deadline date for receipt of applications is July 31, 1991.

Send C.V. to:

Mark Gibson, M.D.

UNIVERSITY OF UTAH SCHOOL OF MEDICINE MATERNAL-FETAL MEDICINE

The Department of Obstetrics and Gynecology is seeking a faculty member for the division of Maternal-Fetal Medicine at the rank of Assistant Professor in the tenure track. The division (as is also true of the residency program) is an integrated one between the University of Utah Medical Center and the LDS Hospital, a large private hospital three miles from the University. Currently the division consists of seven faculty members and a fellow. Applicants must have experience in basic research in reproductive immunology, as well as an interest in teaching and patient care and should be board certified or active candidates for certification in Maternal-Fetal Medicine. Applications must be postmarked by June 1, 1991. Close date June 1, 1991 or until suitable candidate identified.

Dr. James Scott
University of Utah
Department of Obstetrics and Gynecology
Room 2B200
50 North Medical Drive

FELLOWSHIP
MATERNAL-FETAL MEDICINE
JULY, 1992

The Division of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, University MacDonald Womens Hospital, University Hospitals of Cleveland, and Case Western Reserve University, at the instructor level beginning July 1, 1992. Applicants should desire a career in academic medicine and must be Board certified/eligible by the American Board of Obstetrics and Gynecology.

Fellows will be involved in teaching medical students and house officers. The fellowship program emphasizes clinical and basic research in clinical perinatology with a particular interest in ultrasound, and perinatal diagnosis. The individual will also be responsible for some general duties in obstetrics and gynecology.

Applicants should send a curriculum vitae to:

Method Duchon, M.D.
Acting Director, Division of
Maternal-Fetal Medicine
University MacDonald Womens Hospital
University Hospitals of Cleveland
2074 Abington Road
Cleveland, Ohio 44106

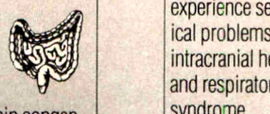
Mosby Year Book

Provide vital information to those who need it most . . .
with article reprints from Mosby–Year Book periodicals

Article reprints are your best means of distributing the information published in Mosby–Year Book's medical, dental, and nursing periodicals. These papers will enhance the value of your information programs.

Not just for authors, reprints are an effective tool for health care professionals, sales and marketing staffs, and advertisers.

Use reprints to:
- Train and educate your sales and marketing staff
- Support your seminar topic
- Inform your health care staff of new developments
- Reach your product users with vital information



Article reprints . . . another valuable service from Mosby–Year Book.

Orders (minimum of 100 copies) of all previous and future articles in Mosby–Year Book periodicals are available from the Publisher.

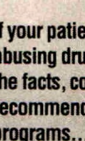
DRUG ABUSE IS CHILD ABUSE



Approximately 80% of the offspring of heroin-dependent women who receive no prenatal care experience serious medical problems such as intracranial hemorrhages and respiratory distress syndrome .

Neonates exposed to cocaine in utero have been documented to experience neurobehavioral abnormalities. They tend to be irritable and easily overstimulated.

The effects of cocaine abuse have been directly linked to certain congenital anomalies in infants, including intestinal atresia, limb reductions, and brain disruptions. These infants are also at a greater risk for congenital heart, urinary tract, and genitourinary defects.

The use of amphetamines during pregnancy may increase the occurrence of cardiovascular defects in the offspring.

If your patients are abusing drugs, tell them the facts, counsel them, recommend treatment programs...help them.

Obstetrics and Gynecology Review Course
June 3-8, 1991 – Chicago
October 21-26 and December 2-7, 1991 – Chicago
Now, your course for exams has practice tests and case-list reviews

Co-sponsored by Penn State University

OBJECTIVES
- Increase basic knowledge and clinical skills in ob-gyn.
- Assist residents and fellows to organize study
- Prepare exam candidates to take their tests
- Provide practicing gynecologists with an update

METHODS
- HOME STUDY MATERIALS with questions and answers
- SEMINAR with projection slides and lecture-note syllabus
- LABORATORY with microscope and glass slides
- PRACTICE EXAMS with both oral and written sections

*"The faculty was outstanding. The most pleasant thing was learning a tremendous amount, not only from world-famous authorities but from people who are relatively unknown as well."**

COURSE AND LOCATION: This course is a comprehensive review and update. The fall course is more clinically oriented. Home study questions are sent upon registration. The course includes lectures with syllabus as well as an opportunity to purchase an unlimited number of optional extra one-on-one sessions with faculty to review your case lists or do mock oral exams. Past participants recommend repeating the course for half price immediately before exams. The course will be at the Hilton Inn, Lisle, Illinois - $85 single; $110 double.

*"...and those little extras...."**

LOWEST AIR FARES: Please call toll-free 1-800-548-8185 for group discounts.

*"...the most education for the money."**

FEES FOR 60 CATEGORY 1 HOURS:
- Practicing Gynecologists: $750
- Residents and Fellows: $500
- Repeating course within 2 years: $375
- Case-list reviews and mock oral exams (half hour sessions): $ 70
- Private mock oral exams: $100
- Optional extra day Dec. 8 (more questions, answers and pathology lab): $150
- **Add 10% within 10 days of the course.**
- Attendees not in course hotel add $20/day.
- Refunds, subject to $50 fee, will be made until the seminar begins.
- A deposit of $50 will reserve your position.
- Most home study materials will be mailed after half of the registration fee is received.

*"...home study material was extremely helpful."**

ACCREDITATION: Penn State is accredited by the Accreditation Council for Continuing Medical Education (ACCME) to sponsor continuing medical education for physicians.
Penn State designates this continuing medical education activity for **60 credit hours** in **Category 1** of the Physican's Recognition Award of the American Medical Association.

*"...remarkably complete and pleasant."**

ORTHO-NOVUM® 777 Tablets

norethindrone/ethinyl estradiol

Low incidence of androgenic side effects

Each white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet contains 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in 28-day regimen contains inert ingredients.

IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables and references. The physician should be thoroughly familiar with the complete prescribing information before prescribing the product.

INDICATIONS AND USAGE: PREVENTION OF PREGNANCY.

CONTRAINDICATIONS: Oral contraceptives should not be used in women who currently have the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Carcinoma of the endometrium or other known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Cholestatic jaundice of pregnancy or jaundice with prior pill use. 8. Hepatic adenomas or carcinomas. 9. Known or suspected pregnancy.

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia, and gallbladder disease, although the risk of serious morbidity or mortality is very small in healthy women without underlying risk factors. The risk of morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks. The information contained in this brief summary is principally based on studies carried out in patients who used oral contraceptives with higher formulations of estrogens and progestogens than those in common use today. The effect of long term use of the oral contraceptives with lower formulations of both estrogens and progestogens remains to be determined. Throughout this brief summary epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease, namely a *ratio* of the incidence of a disease among oral contraceptive users to that among nonusers. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and nonusers. The attributable risk does provide information about the actual occurrence of a disease in the population. For further information, the reader is referred to a text on epidemiological methods. 1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. a. Myocardial Infarction. An increased risk of myocardial infarction has been associated with oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity, and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be two to six. The risk is very low under the age of 30. Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women in their mid-thirties or older with smoking accounting for the majority of excess cases. Mortality rates associated with circulatory disease have been shown to increase substantially in smokers, especially in those 35 years of age and older among women who use oral contraceptives. Oral contraceptives may compound the effects of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see section 9 in WARNINGS). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors. b. Thromboembolism. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the relative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease associated with oral contraceptives is not related to length of use and disappears after pill use is stopped. A two- to four-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. The relative risk of venous thrombosis in women who have predisposing conditions is twice that of women without such medical conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and for two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and during and following prolonged immobilization. Since the immediate postpartum period is also associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than four weeks after delivery in women who elect not to breast feed. c. Cerebrovascular diseases. Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users, for both types of strokes, and smoking interacted to increase the risk of stroke. In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for nonsmokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk is also greater in older women. d. Dose-related risk of vascular disease from oral contraceptives. A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the activity of the progestogen used in the contraceptive. The activity and amount of both hormones should be considered in the choice of an oral contraceptive. Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing 0.035 mg or less of estrogen. e. Persistence of risk of vascular disease. There are two studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for five or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. However, both studies were performed with oral contraceptive formulations containing 50 micrograms or higher of estrogens. 2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE. One study gathered data from a variety of sources which have estimated the mortality rate associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. However, smokers 35 and older and non-smokers 40 and older who use oral contraceptives have a significant increase in mortality higher than those using other methods of birth control. These facts must be weighed in conjunction with failure rates for other methods and the risk associated with subsequent pregnancy. 3. CARCINOMA OF THE REPRODUCTIVE ORGANS. Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. While there are conflicting reports most studies suggest that use of oral contraceptives is not associated with an overall increase in the risk of developing breast cancer. Some studies have reported an increased relative risk of developing breast cancer, particularly at a younger age. This increased relative risk appears to be related to duration of use. Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. 4. HEPATIC NEOPLASIA. Benign hepatic adenomas are associated with oral contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use especially with oral contraceptives of higher dose. Rupture of benign, hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral contraceptive users. However, these cancers are rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users approaches less than one per million users. 5. OCULAR LESIONS. There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia, papilledema, or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately. 6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY. Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. The majority of recent studies also do not indicate a teratogenic effect, particularly in so far as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed two consecutive periods pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued until pregnancy is ruled out. 7. GALLBLADDER DISEASE. Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens. 8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. Oral contraceptives have been shown to cause a decrease in glucose tolerance in a significant percentage of users. This effect has been shown to be directly related to estrogen dose. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects prediabetic and diabetic women in particular should be carefully monitored while taking oral contraceptives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As discussed earlier (see WARNINGS 1a and 1d), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users. 9. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in women taking oral contraceptives, and this increase is more likely in older oral contraceptive users and with extended duration of use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing progestational activity. Women with a history of hypertension or hypertension-related diseases, or renal disease, should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension between former and never users. 10. HEADACHE. The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause. 11. BLEEDING IRREGULARITIES. Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent. 12. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. **PRECAUTIONS:** 1. PHYSICAL EXAMINATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMOTIONAL DISORDERS. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine and liver function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3, increased norepinephrine-induced platelet aggregability. b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radio-immunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINOGENESIS. See WARNINGS section. 10. PREGNANCY. Pregnancy Category X. See CONTRAINDICATIONS and WARNINGS sections. 11. NURSING MOTHERS. Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child. **INFORMATION FOR THE PATIENT: See Patient Package Insert. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS section). Thrombophlebitis and venous thrombosis with or without embolism. Arterial thromboembolism. Pulmonary embolism. Myocardial infarction. Cerebral hemorrhage. Cerebral thrombosis. Hypertension. Gallbladder disease. Hepatic adenomas or benign liver tumors. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea. Vomiting. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Amenorrhea. Temporary infertility after discontinuation of treatment. Edema. Melasma which may persist. Breast changes; tenderness, enlargement, secretion. Change in weight (increase or decrease). Change in cervical erosion and secretion. Diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: Pre-menstrual syndrome. Cataracts. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. Acne. Changes in libido. Colitis. **OVERDOSAGE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea and withdrawal bleeding may occur in females.

Revised 9/89

ORTHO PHARMACEUTICAL CORPORATION

ORTHO

Outstanding Clinical Performance Reflected Inside & Outside

INSIDE

Low Metabolic Impact is reflected inside your ORTHO-NOVUM* 7/7/7 patients†: No clinically significant change in plasma glucose and insulin levels in nondiabetic women.‡[1] Mean values for total cholesterol, HDL or LDL, and blood pressure also show no significant change.§

Excellent Cycle Control is another reflection of outstanding performance with ORTHO-NOVUM 7/7/7. You can expect low discontinuation rates due to breakthrough bleeding, spotting, and amenorrhea.

OUTSIDE

Low Incidence of Androgenic Side Effects—such as acne, oily skin, or hirsutism—is a visible reflection that your patients may notice; another is no clinically significant change in mean body weight. Inside and outside, the outstanding performance of ORTHO-NOVUM 7/7/7 is also an excellent reflection on you.

17 JUL 1991

*Trademark

†Serious as well as minor side effects have been reported with the use of oral contraceptives. The physician should remain alert to the earliest manifestations of any symptoms of serious disease and discontinue oral contraceptive therapy when appropriate.

‡Oral contraceptives have been shown to cause a decrease in glucose tolerance in a significant percentage of users. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents.

§An increase in blood pressure has been reported in women taking oral contraceptives.

Diagnosis and laparoscopic grading of acute salpingitis 1370
David E. Soper, MD
Richmond, Virginia

An overview of the diagnosis and laparoscopic grading of patients with acute salpingitis is presented.

Patient costs for prophylaxis and treatment of obstetric and gynecologic surgical infections 1377
Gary E. Stein, PharmD
East Lansing, Michigan

The use of oral antibiotics to complete a course of treatment can help decrease the high costs of parenteral antibiotic therapy and hospitalization.

Effectiveness of ofloxacin in the treatment of *Chlamydia trachomatis* and *Neisseria gonorrhoeae* cervical infection 1380
Sebastian Faro, MD, PhD, Mark G. Martens, MD, Maurizio Maccato, MD, Hunter A. Hammill, MD, Scott Roberts, MD, and Gerald Riddle, MS
Houston, Texas

This study was undertaken to determine whether the quinolone ofloxacin would be effective in treating cervical infection caused by *Chlamydia trachomatis*.

Susceptibility of female pelvic pathogens to oral antibiotic agents in patients who develop postpartum endometritis 1383
Mark G. Martens, MD, Sebastian Faro, MD, PhD, Maurizio Maccato, MD, Gerald Riddle, MS, and Hunter A. Hammill, MD
Houston, Texas

Susceptibility of the most frequently recovered bacterial pathogens isolated from patients with postpartum endometritis was determined for several oral antimicrobial agents.

New directions in the diagnosis and therapy of urinary tract infections 1387
Robert D. Powers, MD
Charlottesville, Virginia

Selection of appropriate short-course antibiotic therapy for urinary tract infections requires consideration of cost, spectrum of activity, local sensitivity profiles, and patient tolerance.

A randomized trial of ofloxacin versus cefoxitin and doxycycline in the outpatient treatment of acute salpingitis 1390
George D. Wendel, Jr., MD, Susan M. Cox, MD, Roger E. Bawdon, PhD, Sheri K. Theriot, RNC, Molly C. Heard, MA, and Brenda J. Nobles
Dallas, Texas

Oral ofloxacin was found to be as safe and effective as cefoxitin plus probenecid followed by doxycycline in the outpatient treatment of uncomplicated acute salpingitis.

The clinical experience with ofloxacin in the treatment of sexually transmitted diseases 1396
Michael L. Corrado, MD
Raritan, New Jersey

Sexually transmitted diseases caused by *Neisseria gonorrhoeae* and *Chlamydia trachomatis* cause significant morbidity in women. Ofloxacin is a recently introduced single-agent treatment for mixed infections.

Introduction

Sebastian Faro, MD, PhD

Houston, Texas

This symposium was held to present current data on the suitability of the quinolones in the treatment of infections in the gynecologic patient. The data from studies conducted at various hospitals from around the United States will serve to show that the quinolone, ofloxacin, is not only suitable but in some instances may be preferable to antibiotics currently in use.

Ofloxacin is unique in that it is active not only against *Neisseria gonorrhoeae* but also *Chlamydia trachomatis*. In addition, ofloxacin is also active against many gram-negative, facultative, anaerobic bacteria as well as gram-positive aerobes. Ofloxacin also has some activity against *Mycoplasma hominis* and *Ureaplasma urealyticum*. The fact that the quinolones, in general, do not have significant activity against the obligate anaerobic bacteria is of concern, especially when treating the patient with a soft tissue infection such as pelvic inflammatory disease.

The quinolones, especially ofloxacin, have been documented to be effective in the treatment of urinary tract infections, skin and soft tissue infections, and pulmonary infections. The data presented in these proceedings demonstrate that ofloxacin is effective in the treatment of female pelvic infections caused by *N. gonorrhoeae* and *C. trachomatis*. Initial studies have shown that ofloxacin is also effective in the treatment of pelvic inflammatory disease.

Diagnosis and laparoscopic grading of acute salpingitis

David E. Soper, MD
Richmond, Virginia

Pelvic inflammatory disease continues to be a major cause of morbidity in women of reproductive age. Findings of bilateral adnexal tenderness and signs of a lower genital tract infection (mucopus, or leukorrhea, or both) should prompt clinicians to consider the diagnosis of salpingitis in this group of women. Additional signs of infection, such as elevated temperature, palpable adnexal complex, leukocytosis, elevated erythrocyte sedimentation rate, or c-reactive protein, and positive tests for either *Neisseria gonorrhoeae* or *Chlamydia trachomatis* will improve the overall specificity of the clinical diagnosis. Endometrial biopsy offers an acceptable approach to documenting objectively inflammation of the upper genital tract. Diagnostic laparoscopy should be considered in all patients but may be especially helpful for those patients in whom a diagnosis is unclear. A laparoscopic grading system based primarily on tubal mobility and inflammation can be useful in predicting duration of in-hospital therapy and future tubal factor infertility. (Am J Obstet Gynecol 1991;164:1370-6.)

Key words: Laparoscopic grading, pelvic inflammatory disease, obstetric and gynecologic infections, salpingitis

Pelvic inflammatory disease (PID) continues to be a major source of reproductive morbidity in young women.[1] Recent trends have revealed an increased rate and number of hospitalizations for PID as well as increases in ectopic pregnancy rates and infertility.[2-4] In addition, new information suggests that a large number of women suffer from atypical presentations of PID that are never clinically diagnosed or treated.[5,6] A high index of suspicion for the diagnosis of PID, especially in patients with atypical clinical presentations, in conjunction with appropriate clinical evaluation and judicious use of endometrial biopsy and diagnostic laparoscopy, may lead to an earlier diagnosis of PID and possibly decrease the incidence of sequelae.

Pathophysiology

Most PID in the United States is due to ascending infection by cervical microorganisms without prior surgical instrumentation. *Neisseria gonorrhoeae* is able to infect the endometrium and subsequently the fallopian tubes of approximately 15% to 30% of women who harbor this organism in their lower genital tract.[7,8] Cultures from the cervix have confirmed the association of *N. gonorrhoeae* with laparoscopically confirmed salpingitis in between 45% and 82% of cases.[9-12] Cultures from the fallopian tubes and peritoneum have confirmed the presence of *N. gonorrhoeae* in about half of those patients with lower tract infection.

Chlamydia trachomatis is difficult to culture from the upper genital tract, but direct fluorescent antibody stains and serologic studies suggest that the presence of this organism is responsible for as many as 65% of cases of salpingitis in some U.S. populations.[11,13] In addition, laparoscopic studies in Scandinavia have confirmed the presence of *C. trachomatis* in the fallopian tube in between 9% and 30% of patients with PID.[14-16]

Other microorganisms not believed to be sexually transmitted have also been implicated in the pathogenesis of salpingitis. Originally, culdocentesis studies suggested that as many as 80% of cases were associated with mixed infections of both aerobes and anaerobes.[17-19] However, a certain amount of contamination by resident vaginal flora occurred with this procedure.[17-21] North American laparoscopic studies confirm a polymicrobial origin of acute salpingitis in 8% to 40% of cases.[9-12] These microorganisms are particularly found in cases associated with tuboovarian abscesses. Whether these bacteria ascend from a source in the vagina or cervix or become translocated from the bowel lumen is unclear.[22] In unusual cases, appendicitis or Crohn disease can lead to a polymicrobial salpingitis.

This information on the bacterial pathogenesis of PID in North America is collected from only four studies,[9-12] consisting of 148 cases of laparoscopically confirmed salpingitis. Moreover, the data on chlamydia are predominantly based on findings in 48 patients all from

6/0/29321

the same medical center in Seattle.[11, 13] In addition, a substantial number of laparoscopically confirmed cases have negative culture findings of the fallopian tubes and peritoneal fluid. Thus our understanding of the microbial cause of PID is far from complete.

Diagnosis

The patient must come for evaluation for the physician to make a clinical diagnosis of PID. The chief complaint of most patients diagnosed with PID is lower abdominal pain. However, as evidence mounts supporting the existence of atypical salpingitis, other symptoms referable to the genitourinary tract should be considered as potential indicators of upper genital tract infection. These symptoms include dyspareunia, dysmenorrhea, menorrhagia, metrorrhagia, and vaginal discharge.[5] Urinary tract symptoms, such as dysuria and frequency, may also be indicative of infection with a sexually transmitted pathogen.

Infection of the lower genital tract with either *N. gonorrhoeae* or *C. trachomatis* increases a patient's risk for upper tract infection. Risk factors that promote infection with these microorganisms include age younger than 25 years and multiple sexual partners. Patients with bacterial vaginosis and those who frequently douche may also have an increased risk of PID.[23, 24] Iatrogenic procedures, such as intrauterine device insertions and dilation and curettage, which breech the cervical mucous barrier and place potentially pathogenic microorganisms into the endometrium, can also lead to upper tract infection.

Other signs that may herald the onset of PID are breakthrough bleeding on the birth control pill or persistent vaginal spotting after elective termination of pregnancy. These complaints commonly result from an endometritis, which, if not treated, may progress to salpingitis.

Physical findings consistent with a diagnosis of PID include the presence of cervical mucopus, leukorrhea, or both.[25, 26] After cleansing the ectocervix with a large cotton swab, a cotton swab should be placed into the endocervical canal and inspected for a green or yellow color. In addition, Gram's stain of this material after it is streaked on a slide should be examined microscopically for the presence of white blood cells. More than 30 polymorphonuclear cells per oil immersion field correlates with mucopurulent cervicitis and chlamydial or gonococcal infection.[27] In addition, microscopy of a wet mount of the vaginal secretions should reveal a ratio of more than one white blood cell per epithelial cell in patients with PID. In a patient with lower abdominal pain, the presence of bilateral adnexal tenderness together with signs of a lower genital tract infection (mucopus, leukorrhea, or both) is associated with the laparoscopically confirmed diagnosis of acute salpingitis in 65% of cases.[28]

Additional clinical findings supportive of infection and inflammation improve the specificity of the clinical diagnosis of PID. Elevated temperature, palpation of an adnexal complex, leukocytosis, elevated erythrocyte sedimentation rate or C-reactive protein, purulent material obtained by culdocentesis, or a positive test for a lower genital tract infection with *N. gonorrhoeae* or *C. trachomatis* are considered adjunctive criteria for the diagnosis of PID. The specificity of the clinical diagnosis of PID increases to greater than 90% when two or more of these criteria are associated with the findings of pain, adnexal tenderness, and leukorrhea.[29] The take-home message is clear. Although diagnostic laparoscopy is useful in obtaining reliable cultures and assessing the severity of disease in overt cases of salpingitis, it is most helpful in confirming the diagnosis of salpingitis in the patient with a mild clinical presentation.

Endometrial biopsy and culdocentesis can also be used to confirm the presence of inflammation of the upper genital tract. In comparison with laparoscopically confirmed salpingitis, endometritis had a positive predictive value of 84% in the diagnosis of PID.[30] Moreover, when five or more neutrophils per ×400 field in endometrial surface epithelium are associated with one or more plasma cells per ×120 field in the endometrial stroma, a sensitivity of 92% and a specificity of 87% for predicting the diagnosis of both laparoscopically confirmed acute salpingitis and a positive upper genital tract culture are noted.[31] Most recently, endometrial biopsy was more than 90% specific in predicting histopathologic evidence of salpingitis.[32] Culdocentesis showing purulent material has also been suggested as a supportive criterion for the diagnosis of PID.[33] This finding in conjunction with the clinical signs and symptoms of PID should have a high positive predictive value if an adequate specimen can be obtained. Unfortunately, only 60% of patients with a clinical diagnosis of PID will have a positive test result because of technical difficulties, absence of cul-de-sac pus, or possibly incorrect diagnosis.[34] Culdocentesis is associated with significant patient discomfort and for this reason does not enjoy widespread use for the diagnosis of either PID or ectopic pregnancy. On the other hand, endometrial biopsy is highly recommended in the workup of a patient suspected of having PID. The procedure is technically uncomplicated and can be performed by both primary care physicians and gynecologists. It allows the clinician to partially evalute the upper genital tract but stops short of requiring general anesthesia and laparoscopy. When performed with the Pipelle endometrial suction curette, only minor discomfort is experienced by the patient.

Table I. Clinical criteria for the diagnosis of PID

Westrom and Mardh[38]	*Hager*[33]	*Suggested*
Major criteria (all must be present)		
Abdominal pain	Abdominal tenderness	Adnexal tenderness
Adnexal tenderness	Cervical motion tenderness	Signs of a LGTI
Signs of a LGTI	Adnexal tenderness	
Minor criteria (additional criteria increase the specificity of the diagnosis)		
Palpable adnexal mass	Gram's stain of endocervix—positive for GND	Endometrial biopsy = endometritis
ESR ≥ 15 mm/hr	Temperature > 38° C	Elevated CRP or ESR
Temperature > 38° C	Leukocytosis (> 10,000)	Temperature > 38° C
	Purulent material by culdocentesis	Leukocytosis
	Pelvic complex by examination or sonography	Positive test for chlamydia or GC

LTGI, Lower genital tract infection; *ESR*, erythrocyte sedimentation rate; *GND*, gram-negative diplococci; *CRP*, C-reactive protein; *GC*, *N. gonorrhoeae*.

The clinical criteria for the diagnosis of PID have never been validated in large prospective studies. Currently two similar sets of guidelines for the diagnosis of PID have been suggested. Jacobson and Westrom were[28] the first to evaluate the accuracy of conventional signs and symptoms of PID as assessed by the visual confirmation of acute salpingitis. Diagnostic accuracy of acute salpingitis was improved by increasing the number of positive parameters. Westrom suggested that the basis for the diagnosis of PID should be a minimum of three major criteria, with supportive signs, laboratory tests, or both improving the specificity of the diagnosis (Table I). Of particular importance is Westrom's uniform finding of a marked increase in the number of inflammatory cells in the wet smear of the vaginal secretions of women with PID.[25] It appears that this simple test can be used to exclude the possibility of PID in women with abdominal pain.

In a separate analysis of Westrom's data, purulent vaginal discharge, an elevated erythrocyte sedimentation rate, positive culture for *N. gonorrhoeae*, adnexal swelling on bimanual examination, and a temperature greater than or equal to 38° C were good predictors of laparoscopically confirmed salpingitis.[29] Hager et al.[33] published similar guidelines suggesting that clinicians rely on three major clinical signs and at least one of five supportive parameters. Their guidelines eliminate the necessity for a chief complaint of abdominal pain, an important improvement if we accept the probability that many patients with atypical ("silent") salpingitis may not have abdominal pain.[5,6] However, they diminish the importance of abnormal vaginal secretions, although a Gram's stain of the endocervix revealing gram-negative diplococci is an adjunctive criterion (Table I). As Hager et al.[33] point out, it is important to use criteria that will not exclude patients with mild disease. A compromise between the two published guidelines should allow the desired high sensitivity with respect to the diagnosis of PID. Patients who come to the clinician with any symptoms referable to the genitourinary tract, have bilateral adnexal tenderness during bimanual pelvic examination, and have signs of an infection of the lower genital tract, specifically microscopy of a wet mount of the vaginal secretions showing increased numbers of inflammatory cells, should have a diagnosis of PID considered. Endometrial biopsy should also be considered to confirm the clinician's suspicion of upper genital tract inflammation. Further study and validation of clinical diagnostic criteria should be undertaken, but until that is accomplished, this approach will allow potential morbidity from atypical salpingitis to be minimized. This will inevitably lead to the treatment of patients for PID who in reality do not have salpingitis. However, many of these patients will have endocervicitis or endometritis without salpingitis, and therefore antibiotic treatment is indicated in any case. Because of the expected low specificity of the diagnosis of PID with respect to confirmed salpingitis in these cases, rigorous scientific study of this disease will continue to require laparoscopy as the gold standard for the diagnosis and evaluation of the severity of disease.

The clinical grading[33] or staging[35] of salpingitis may be helpful in clinical triage regarding whether a patient should be admitted to the hospital, but its relationship to laparoscopic findings has not been determined. At the Medical College of Virginia, patients admitted with four-quadrant rebound and significant elevation in temperature are more likely to have a laparoscopically mild salpingitis (tubes freely mobile and ostia appear patent) rather than a ruptured tuboovarian abscess (unpublished observations). Moreover, bimanual pelvic examination in patients with significant direct and indirect tenderness can rarely be performed sufficiently to determine if the patient has a palpable adnexal complex, which leads to incorrect clinical staging in many patients. It is clear that the clinical severity of disease

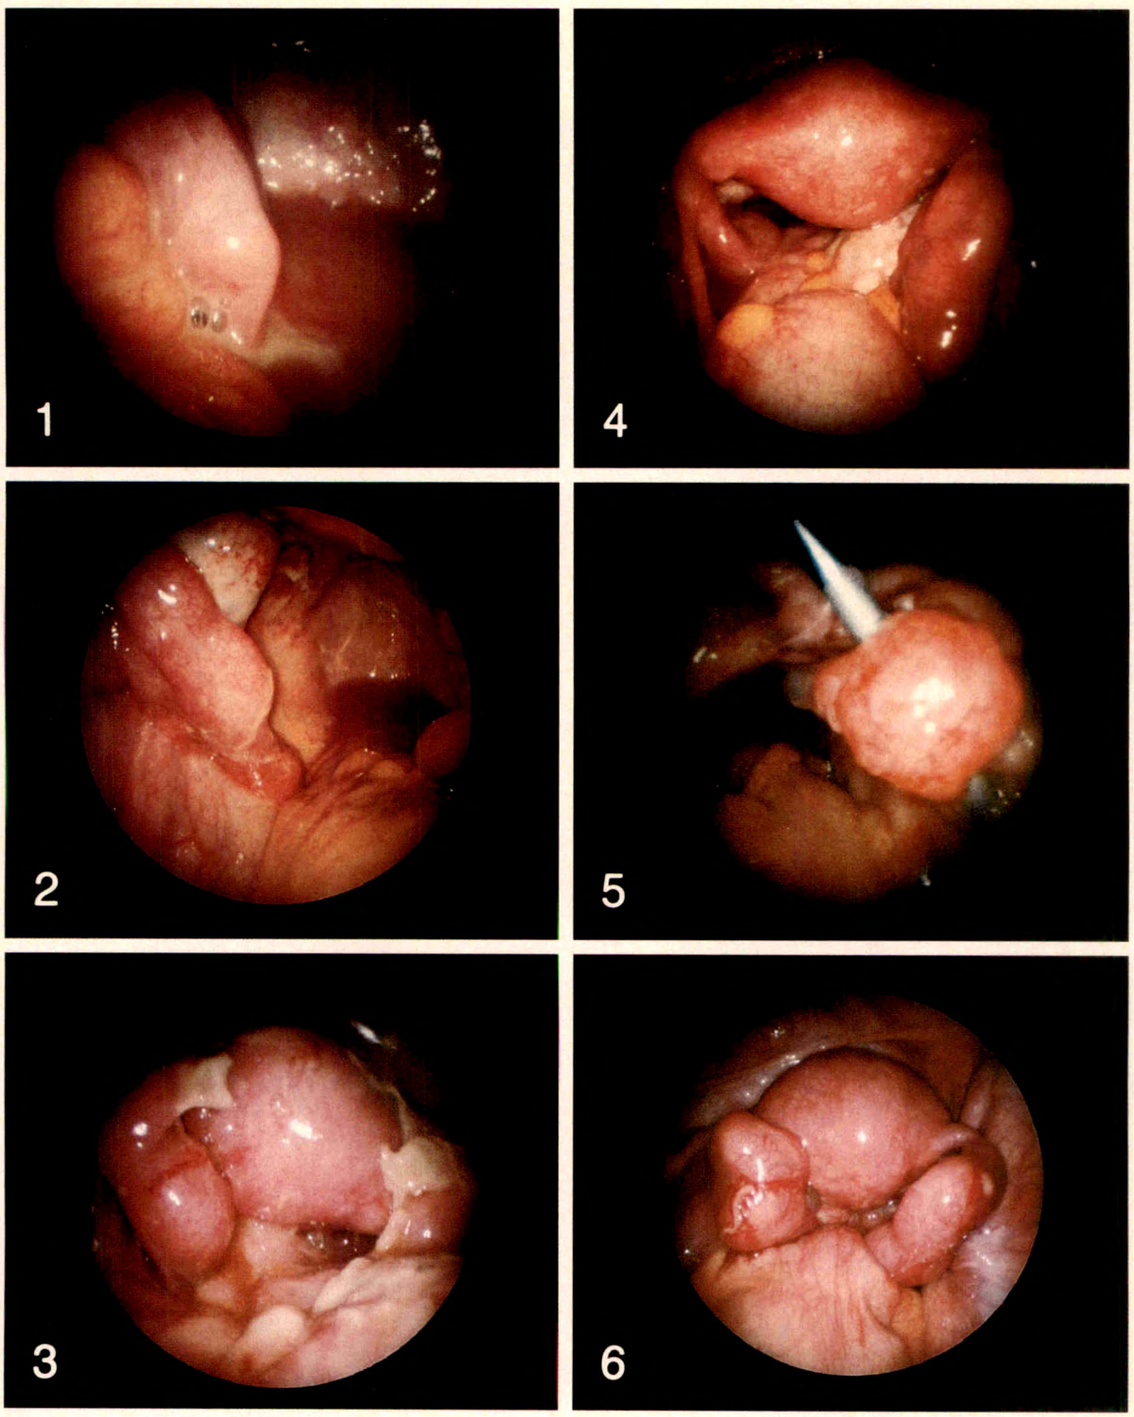

Fig. 1. A freely mobile, patent fallopian tube with purulent material exuding from the ostia, is seen resting in a pool of serosanguinous, purulent exudate. **Fig. 2.** The left fallopian tube is covered with a sticky exudate. A serosanguinous, purulent exudate is seen in the cul-de-sac. **Fig. 3.** Patchy fibrin deposits are seen on the serosal surfaces of the tubes. **Fig. 4.** The left fallopian tube is adherent to the posterior aspect of the broad ligament and an adhesion can be seen extending from the tube to the bowel. **Fig. 5.** Fimbria of the right fallopian tube are agglutinated and swollen in a patient with moderate salpingitis. **Fig. 6.** Bilateral pyosalpinx are noted. Puncture wounds from an 18-gauge spinal needle are noted to exude purulent material.

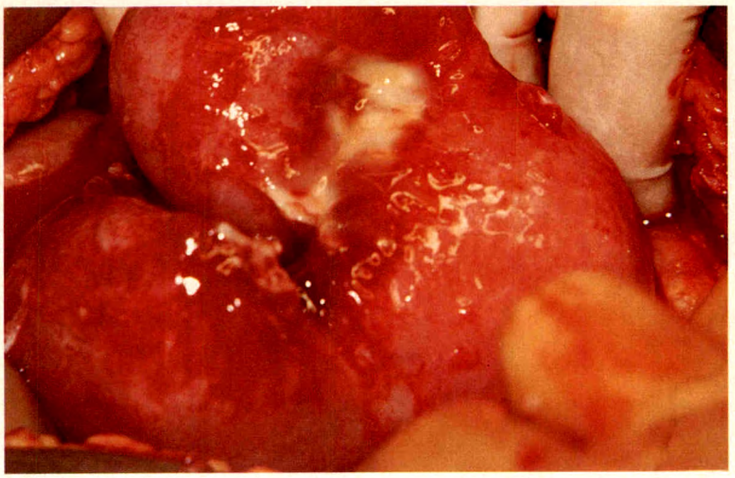

Fig. 7. A left tuboovarian abscess is lifted out of an incision. The uterus is seen anteriorly. This patient required a total abdominal hysterectomy–bilateral salpingo-oophorectomy for failure to respond to antibiotic therapy.

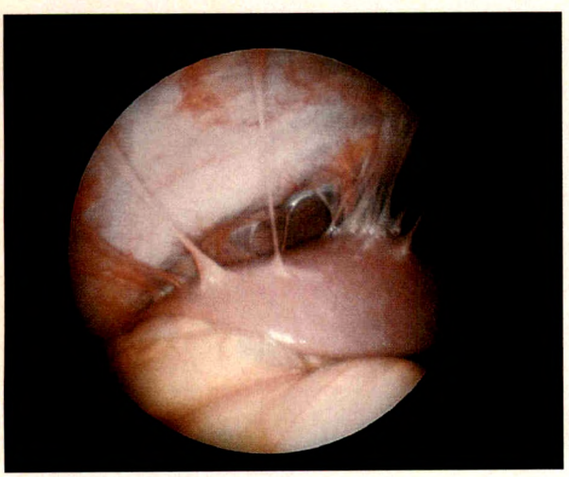

Fig. 8. Violin-string adhesions are visualized in this patient with Fitz-Hugh–Curtis syndrome.

as assessed by physical examination has no relationship to the grade of laparoscopically confirmed salpingitis with respect to tubal mobility and patency.[36]

Laparoscopic grading

The minimum criteria for the visual confirmation of acute salpingitis include (1) pronounced hyperemia of the tubal surface, (2) edema of the tubal wall, and (3) a sticky exudate on the tubal surface and from the fimbriated ends when patent.[28] In some cases erythema and edema can be overinterpreted because of observer bias.[32] For this reason, visual confirmation of salpingitis without the presence of exudate may be erroneous (false positive).[30] Evaluation of the peritoneal exudate to document the presence of inflammatory cells is suggested. Peritoneal fluid in normal patients and in those with endometriosis will contain predominantly macrophages.[37] Peritoneal fluid cytologic examinations in patients with acute salpingitis will inevitably reveal a predominance of neutrophils.[30] The value of histologic evaluation of minute fimbria biopsy specimens to confirm pathologically the visual diagnosis of salpingitis has yet to be defined. However, Sellors et al.[32] have demonstrated the importance of minute fimbria biopsy as an additional objective parameter in preventing both a false-positive and false-negative laparoscopic diagnosis of salpingitis. Most important, patients who do not meet the minimum criteria for visual confirmation of salpingitis may actually have subclinical disease, possibly because of an endosalpingitis. Minute fimbria biopsy may play a role in defining this subset of women with visually mild salpingitis. Moreover, it is imperative to perform an endometrial biopsy during the performance of the diagnostic laparoscopy to add objective evidence of upper genital tract inflammation.

Criteria for the severity of salpingitis by laparoscopic examination have been reported by Westrom.[38] These criteria do not differ significantly from the refined criteria of Hager et al.[33] Mild salpingitis is associated with the above minimum visual criteria. In addition, the tubes are freely mobile and the ostia appear patent (Fig. 1). The tube may be covered with a stickly exudate (Fig. 2). Moderate salpingitis is associated with more pronounced inflammation. Patchy fibrin deposits are on the serosal surfaces and the tubes are not freely movable (Fig. 3). Adhesions are loose and moist, and a paraphimotic appearance may be present (Fig. 4). The fimbria may appear adherent (Fig. 5). Severe sal-

pingitis reveals intensely congested peritoneal surfaces. Pelvic organs adhere to each other, and pyosalpinx (Fig. 6) or tuboovarian complex formation (Fig. 7) may be present.

In some cases both adnexa are not equally affected by the inflammatory process. Grading should be performed with respect to each individual adnexal finding. The overall grade should reflect the most severe finding. For example, a patient with a right-sided pyosalpinx but an otherwise mildly involved left tube would warrant an overall grade of severe. The severity of the grade of salpingitis is, for the most part, dependent on tubal mobility and patency. Therefore an acute infectious process superimposed on chronic adhesive changes, possibly because of a previous episode of salpingitis, will be graded as more advanced when in reality the amount of purulent exudate, side-to-side agglutination, and tubal edema and erythema may be less than an initial mild grade of gonococcal salpingitis. Despite this possibility, patients with a more severe grade of salpingitis require a longer duration of antibiotic therapy before reaching a therapeutic response.[11] As previously mentioned, the clinical severity of disease does not predict the severity of tubal disease. In fact those patients with milder disease, as seen in patients with chlamydial salpingitis, actually have more severe inflammatory changes in the tubes than would be expected from a relatively benign clinical course.[31]

Sequelae

The sequelae resulting from salpingitis is directly proportional to the severity of the inflammatory reactions of the tubes. The incidence of infertility caused by a single episode of severe salpingitis appears to be close to 30% and falls to a low of 6% in patients with only mild disease.[38] Patients taking oral contraceptives at the time of their diagnosis appear to have an improved prognosis, not only are they less likely to develop salpingitis initially, but they generally have a less severe grade of salpingitis if they do develop upper tract disease.[39] Rates of tubal factor infertility also increase with subsequent episodes of PID. The patient with three or more episodes of salpingitis runs a 50% to 60% risk of tubal factor infertility.[38] Despite earlier data to the contrary, a prognosis of fertility does not appear to be related to the microbial cause of acute salpingitis.[40]

The Fitz-Hugh–Curtis syndrome is characterized by violin-string adhesions between the liver and anterior abdominal wall in women with gross pathologic evidence of prior tubal infection. It consists of a continuum of acute perihepatitis associated with acute salpingitis followed by the formation of perihepatic adhesions (Fig. 8). Occasionally chronic right upper quadrant pain necessitating laparoscopic lysis of adhesions occurs.[41]

Summary

Although much has been learned about the pathophysiology and diagnosis of PID during the past decade, much more remains to be investigated. Unified clinical diagnostic criteria must be developed and validated in large prospective studies. Less invasive methods for confirming the diagnosis and assessing the severity of tubal disease also must be evaluated. Most important, further clarification of the pathophysiology and clinical presentation of atypical or "silent" salpingitis must be elucidated. Only in these ways can strategies for the prevention and intervention be developed to decrease the serious sequelae associated with PID.

Patient costs for prophylaxis and treatment of obstetric and gynecologic surgical infections

Gary E. Stein, PharmD
East Lansing, Michigan

The use of newer broad-spectrum antimicrobials for prophylaxis and treatment in obstetric and gynecologic surgery can reduce patient morbidity and hospital costs. For prophylaxis, a single dose of a cephalosporin with a long elimination half-life can be as effective as a more prolonged course. Single-dose prophylaxis reduces not only toxicity and cost to the patient but also the likelihood of colonization of the vagina by resistant organisms. Treatment regimens for postoperative pelvic infections should have broad-spectrum coverage against aerobic and anaerobic pathogens to ensure high cure rates and prevent subsequent abscess formation. With the introduction of newer cephalosporins and penicillin combinations that include a β-lactamase inhibitor, it is now possible to treat these polymicrobial infections effectively with monotherapy. Compared with traditional antibiotic combinations, these drugs can reduce side effects and the costs of drug administration as well as the need for therapeutic monitoring. The use of oral antibiotics to complete a course of treatment can also help decrease the high costs of parenteral antibiotic therapy and hospitalization. (AM J OBSTET GYNECOL 1991;164:1377-80.)

Key words: Costs, prophylaxis, obstetric and gynecologic surgical infections, quinolones

Infection after obstetric and gynecologic surgery continues to be an important source of patient morbidity despite improved surgical techniques and the use of prophylactic antibiotics. The cause of pelvic infections after common procedures such as vaginal hysterectomy or cesarean section has now been better defined and often involves both aerobic and anaerobic bacteria.[1] In addition to well-recognized pathogens such as β-hemolytic streptococci, *Escherichia coli, Neisseria gonorrhoeae, Chlamydia trachomatis,* and coagulase-negative staphylococci, anaerobic bacteria are commonly recovered in patients with postoperative endomyometritis or pelvic cellulitis.[2] The most common anaerobic organisms isolated include peptostreptococci, peptococci, *Bacteroides bivius, B. disiens, B. fragilis,* and *Fusobacterium* species. Because of the polymicrobial nature of these infections, it is important to use treatment regimens that have a broad spectrum of activity that includes aerobic and anaerobic bacteria.

Prophylaxis

Antibiotics given before obstetric and gynecologic surgery can significantly decrease the number of operative site infections, reduce febrile morbidity, and shorten hospital stay.[3] The overall effectiveness of antibiotic prophylaxis is influenced by several factors, which include surgical technique, duration of the surgery, and the antibiotic chosen. It is vitally important that the antibiotic has not only good activity against potential pathogens but also attains high tissue levels at the time of bacterial contamination. Shapiro et al.[4] found that the salutary effect of prophylactic cefazolin diminished rapidly with increased duration of surgery.

The ideal prophylactic antibiotic should be nontoxic, effective against most organisms encountered in the endogenous flora, long acting, and inexpensive. Although numerous antibiotics have been found to be effective prophylactic agents, cefazolin continues to be the recommended choice in gynecologic surgery.[5] This cephalosporin has been studied extensively and has the advantage of a long half-life. A cost-benefit analysis of a three-dose regimen of cefazolin for prophylaxis found an average benefit of $492 in vaginal hysterectomy and a $102 savings in patients undergoing abdominal hysterectomy.[6] Longer durations of prophylaxis or the use of more expensive cephalosporins were found to diminish these cost benefits. Zhanel et al.[7] calculated that approximately $25,000 could be saved from their annual pharmacy budget if cefazolin was substituted for more expensive antimicrobials for prophylaxis in obstetric and gynecologic surgery.

Because anaerobes such as *B. fragilis* are frequently recovered in postoperative pelvic infections, the need for prophylactic antibiotics with activity against these

6/0/29322

organisms has been advocated by some investigators. Hamond et al.[8] demonstrated equal effectiveness of cephalothin and metronidazole in preventing infection after vaginal hysterectomy. This suggests that prophylactic agents need not be effective against all possible pathogens, but activity against either aerobic or anaerobic flora would reduce postoperative infections. Other investigations have shown that antibiotics that are active against both aerobic and anaerobic organisms were more effective than agents with just an aerobic or an anaerobic spectrum. This has led to studies with broad-spectrum antibiotics such as cefoxitin, piperacillin, and more recently cefotetan. These antibiotics are active against aerobic and anaerobic pathogens associated with pelvic infections and have been found to be effective prophylactic agents. In addition, Stiver et al.[9] observed a lower fever index and shorter hospital stays in patients in whom infections developed after cesarean section when they received prophylactic cefoxitin compared with cefazolin. Cefotetan has an advantage over these other antibiotics because of its extended half-life. A single, perioperative dose of cefotetan has been found to be as safe and effective as a three-dose regimen of cefoxitin for prophylaxis in cesarean section and hysterectomy.[10, 11]

Antibiotic prophylaxis has become standard care for obstetric and gynecologic operations, but the most appropriate agent and duration of antibiotic administration have not been defined precisely. It appears that a single dose of an antibiotic with a long half-life can be as effective as prolonged courses of prophylaxis. A single, preoperative dose has the potential advantages of reduced cost and toxicity to the patient as well as reduced likelihood of increased colonization of the vagina by resistant organisms.

Treatment

With the recognition that postoperative pelvic infections are frequently polymicrobial in nature, newer treatment strategies have recommended antibiotic regimens with activity against aerobic and anaerobic pathogens.[12] The rationale for these recommendations has been formulated from animal models such as the intraabdominal sepsis model of Weinstein et al.[13] These investigators found that untreated peritonitis resulted in a high mortality rate that was caused by gram-negative facultative bacteria such as *E. coli*. Abscesses observed in surviving animals appeared to be caused by microbial synergy between facultative and anaerobic bacteria. Only antibiotic regimens with both aerobic and anaerobic coverage were able to decrease mortality and the subsequent development of abscesses.[14] Although treatment of these polymicrobial infections has traditionally been with a combination of an aminoglycoside plus clindamycin, single broad-spectrum antibiotics are also effective. Monotherapy helps avoid side effects as well as the increased indirect costs of drug administration and therapeutic monitoring.

Several newer antimicrobials have been suggested as alternatives to combination therapy. These include cephalosporins (cefoxitin and ceftizoxime), extended-spectrum penicillins (mezlocillin and piperacillin), monobactams (aztreonam), carbapenems (imipenem), and fluoroquinolones (ofloxacin and ciprofloxacin).[15] These antibiotics are generally safe and effective alternatives to aminoglycosides, but several lack adequate anaerobic coverage and still require the addition of clindamycin or metronidazole in the treatment of mixed anaerobic-aerobic infections. In addition, some of these drugs are not suitable for monotherapy because resistance or superinfection commonly develops during therapy. Numerous clinical trials have demonstrated the effectiveness of cefoxitin, and this antibiotic has generally been the preferred single agent for therapy of postoperative pelvic infections during the past decade.[16] Recently newer cephalosporins such as ceftizoxime and cefotetan have been found to be effective in the treatment of acute obstetric and gynecologic infections.[17] Because these antibiotics require fewer daily doses, they have become cost-effective alternatives to cefoxitin. Sochalski et al.[18] found that the total cost per day of cefotetan was approximately 40% lower than cefoxitin in their hospital. One potential drawback to the use of these newer cephalosporins is their higher rates of resistance against clinically important anaerobic bacteria (Table I).[19]

Of the newer broad-spectrum antimicrobials that have been introduced during the past few years, the single antibiotic combinations may prove to be the most useful for empiric treatment of polymicrobial infections. Combinations of older penicillins, such as ampicillin and ticarcillin with a β-lactamase inhibitor, are active against a large number of facultative bacteria. In addition, they are essentially always active against anaerobes and need not be tested for clinical purposes.[20] Clinical evaluations of ticarcillin-clavulanate and ampicillin-sulbactam have shown that they are as effective as cefoxitin, as well as combination therapy, in the treatment of pelvic infections.[21, 22] These single antibiotic combinations need to be administered more frequently than some of the newer cephalosporins, which makes them more costly to administer in the hospital. On the other hand, fewer treatment failures may occur with these drugs because of their expanded spectrum.[23] Imipenem-cilastatin is another single antibiotic combination that has been effective in the treatment of obstetric and gynecologic infections.[24] Unlike sulbactam and clavulanate, cilastatin does not inhibit bacterial β-lactamases but prevents renal enzymes from inactivating imipenem. Imipenem has the broadest coverage of

Table II. Patient costs for monotherapy of postoperative pelvic infections

Drug	Dose/schedule	Cost per day*
Cefotetan	2 gm every 12 hr	$ 62
Ampicillin/sulbactam	3 gm every 6 hr	$ 84
Ticarcillin-clavulanate	3.1 gm every 6 hr	$ 84
Ceftizoxime	2 gm every 8 hr	$ 93
Cefoxitin	2 gm every 6 hr	$108
Imipenem	1 gm every 8 hr	$144

*Average wholesale cost + administrative fee ($10).

any single antibiotic, but because of its high cost it should be reserved for resistant cases (Table II).

Because of the high cost of parenteral therapy and hospitalization, oral antibiotics should be considered to complete a course of therapy. The single antibiotic combination of amoxicillin-clavulanate is the oral equivalent of ampicillin-sulbactam and is useful in the treatment of polymicrobial infections.[25] Other antibiotic combinations, such as a fluoroquinolone plus metronidazole, can also be effective oral therapy. The fluoroquinolones are broad-spectrum antibiotics and attain high concentrations in reproductive tissues.[26] Ofloxacin may be especially useful in some patients because of its increased activity against *Chlamydia* and *Mycoplasma*.[27-29]

Conclusion

A large body of knowledge now exists concerning appropriate prophylaxis and treatment of obstetric and gynecologic infections. Effective prophylaxis can be accomplished with a single dose of a long-acting cephalosporin, such as cefazolin or cefotetan. Empiric treatment of postoperative pelvic infections requires an antimicrobial regimen with coverage against aerobic and anaerobic organisms. Monotherapy with a broad-spectrum cephalosporin or a penicillin combination that includes a β-lactamase inhibitor has been found to be as effective as combination chemotherapy. The conversion to oral antibiotics, when appropriate, will also help decrease treatment costs and hospital stay.

Effectiveness of ofloxacin in the treatment of *Chlamydia trachomatis* and *Neisseria gonorrhoeae* cervical infection

Sebastian Faro, MD, PhD, Mark G. Martens, MD, Maurizio Maccato, MD, Hunter A. Hammill, MD, Scott Roberts, MD, and Gerald Riddle, MS

Houston, Texas

Forty patients with cervical infection caused by *Chlamydia trachomatis* were treated with ofloxacin (20) or doxycycline (20). Ofloxacin was successful in eradicating *C. trachomatis* from all 20 (100%) patients. Doxycycline was effective in 18 of 20 (90%) patients. Three patients had a concomitant cervical gonococcal infection. All three were successfully treated: one with ofloxacin and two with doxycycline. Ofloxacin, 300 mg, taken twice daily for 7 days, is effective in eradicating endocervical *C. trachomatis* infection. (Am J Obstet Gynecol 1991;164:1380-3.)

Key words: Cervicitis, *C. trachomatis, N. gonorrhoeae*

Antibiotic therapy for the treatment of cervicitis caused by *Neisseria gonorrhoeae* is predicated on the suspicion that a penicillinase-producing strain may be present. In addition, *N. gonorrhoeae* is known to have both plasmid and chromosomal resistance, thus making penicillin, tetracycline, and cefoxitin less effective.[1] In a recent study of 6204 gonococcal isolates from 21 locations within the United States, 21% were resistant to penicillin, tetracycline, cefoxitin, or spectinomycin.[2] Although all of the isolates tested were sensitive to ceftriaxone, there have been reports of decreasing sensitivity to ceftriaxone among isolates from Southeast Asia.[3] Thus the current recommendation by the Centers for Disease Control to treat all gonococcal cervicitis and urethritis with ceftriaxone continues to be appropriate.[4] However, the current widespread use of ceftriaxone necessitates continued monitoring of isolates for resistance to ceftriaxone.

Chlamydia trachomatis is considered the most common sexually transmitted organism. Like *N. gonorrhoeae,* it is responsible for pelvic inflammatory disease, ectopic pregnancy, and infertility, in addition to neonatal conjunctivitis and pneumonitis. *C. trachomatis* and *N. gonorrhoeae* may be found as coinfections in 30% to 60% of patients, and up to 15% of *N. gonorrhoeae* may be

6/0/29323

resistant to tetracycline.[5] Therefore the regimen recommended by the Centers for Disease Control, that is, to treat cervical infection with à combination of ceftriaxone plus doxycycline, seems appropriate.

The present study was undertaken to determine if the quinolone ofloxacin would be effective in treating cervical infection caused by *C. trachomatis*. Preliminary in vitro and in vivo data suggested that ofloxacin has activity against both *C. trachomatis* and *N. gonorrhoeae*,[6,7] whereas the quinolone ciprofloxacin does not appear to be especially effective in the treatment of chlamydial infection.[8] Ofloxacin is not affected by penicillin-binding proteins, penicillinase or β-lactamase, and so forth, and therefore would not be inhibited by penicillinase- or β-lactamase–producing or tetracycline-resistant strains of *N. gonorrhoeae*.

Methods

Patients attending the Harris County Gynecologic Clinic (low income) who were 18 years of age or older and positive for cervical infection with *C. trachomatis* alone or in conjunction with *N. gonorrhoeae* were randomized to receive treatment with either ofloxacin or doxycycline. Ofloxacin was administered in a dose of 300 mg, orally, twice a day, and doxycycline, 100 mg, was given orally, twice daily, for 7 days. Antibiotics were assigned according to a computer-generated randomization schedule provided by the Ortho Pharmaceutical Corp. Before enrollment into the study, all patients gave written informed consent.

On admission to the study, a complete medical history was obtained and a physical examination was performed. Venous blood was obtained for a complete blood count, white blood cell differential, platelet count, serum glucose, alkaline phosphatase, creatinine, blood urea nitrogen, total bilirubin, and aspartate aminotransferase. A urinalysis was also performed.

Specimens were obtained from the endocervix by gently wiping away vaginal discharge from the portio of the cervix with a large procto swab. A Dacron swab was then inserted into the endocervical canal, rotated in a clockwise manner for 30 to 40 seconds, and withdrawn. The initial swab was immediately placed into chlamydial transport medium, 2-SP (sucrose-phosphate) obtained from Bartels Immunodiagnostics, Bellevue, Wash. The specimens were immediately taken to the laboratory and processed for inoculation of cycloheximide-treated McCoy cells.[9] Inclusions were identified with monoclonal fluorescent antibody (obtained from Ortho Diagnostic Systems, Raritan, N.J.). A second swab was used to obtain a specimen for *N. gonorrhoeae* from the endocervix. This specimen was immediately streaked onto modified Thayer-Martin medium containing less than 3 μg of vancomycin. The inoculated plates were incubated at 35° C in 5% carbon dioxide environment. Isolates were confirmed by standard microbiologic methods. A Gram's stain was also performed on a specimen obtained from the endocervix.

The specimens were obtained from the endocervix with sterile cotton-tipped applicators and placed in *Mycoplasma* and *Ureaplasma* transport media (2-SP). The specimens were then inoculated on A-7 media (Scott Laboratories, Fiskeville, R.I.) and incubated at 35° C under anaerobic conditions.

Patients found positive for *C. trachomatis* and also those coinfected with *N. gonorrhoeae* were enrolled into the study. After completion of either antibiotic, patients were asked to return for follow-up evaluation between days 12 and 16 and days 28 and 35. At both visits pelvic examinations were performed, and endocervical specimens were obtained for test of cure. Repeat blood tests and urinalysis were obtained on the first follow-up visit only, unless an abnormal test was obtained.

Patients were considered cured if the follow-up culture for *C. trachomatis* and *N. gonorrhoeae* (if present originally) did not find the organism. A treatment failure was defined as persistence of the original offending pathogen on first follow-up visit. Patients who failed to complete the prescribed course of antibiotics, failed to return for follow-up evaluation, or took an additional antibiotic other than ofloxacin or doxycycline were considered nonevaluable. Only one patient was dropped from the study because she was 17 years old.

Sexual partners were afforded the opportunity of treatment with oral doxycycline, 100 mg, twice daily, for 7 days. Patients were given a supply a condoms and asked to use them for the duration of the study. In addition to the use of condoms, oral contraceptives were usually found to be used by most of the patients. All patients had a negative pregnancy test result before enrollment.

Patient compliance was assessed by having the patients return their pill container for pill counts.

Results

A total of 40 evaluable patients were enrolled into the study. Most patients were black (58%), 20% were Hispanic, and 22% were of other racial or ethnic backgrounds. The average age of the study population was 19 years. Although the population was relatively young (18 to 21 years of age), 55% of the patients had been pregnant at least once. Approximately 93% of the patients used some form of birth control, with 85% taking oral contraceptives. The study population reported a previous history of 19 episodes of sexually transmitted disease.

Among the 40 patients who had positive findings of *C. trachomatis*, only three also harbored *N. gonorrhoeae* (7.5%). All patients treated with ofloxacin were cured

Table I. Microbiologic results

	Chlamydia		*Neisseria*		*Mycoplasma*		*Ureaplasma*	
	Pre	*Post*	*Pre*	*Post*	*Pre*	*Post*	*Pre*	*Post*
Ofloxacin	20	0	1	0	10	5	14	13
Doxycycline	20	2	2	0	11	9	12	9

of the *C. trachomatis* infection (100% eradication), whereas 18 of 20 (90%) patients treated with doxycycline were cured (Table I). All three patients found to be infected with *N. gonorrhoeae,* one treated with ofloxacin and two with doxycycline, were cured.

Mycoplasma was found in 10 (50%) of the patients treated with ofloxacin. *Mycoplasma* was eradicated from half of the patients treated with ofloxacin. Approximately 55% (four patients) of those treated with doxycycline were *Mycoplasma* positive. Only two patients (10%) were found to be free of *Mycoplasma* after treatment with doxycycline. *Ureaplasma* was found in 70% of ofloxacin-treated patients and 60% of those treated with doxycycline. Neither antibiotic was very effective in eradicating *Ureaplasma* from the endocervix (Table I).

Comment

Although the study reported here does not contain a large number of patients, it demonstrates that ofloxacin is a suitable agent for the treatment of *C. trachomatis.* In fact, ofloxacin was as effective as doxycycline in eradicating *C. trachomatis* from the endocervix. These results were similar to those reported by other investigators in the treatment of female pelvic infections caused by *C. trachomatis.*[10, 11]

Mycoplasma and *Ureaplasma* are common inhabitants of the female lower genital tract. Their role as pathogens has not been well established, because these organisms have been retrieved frequently from healthy vaginas. However, they have been implicated in chorioamnionitis, bacterial vaginosis, infertility, and abdominal wound infections after cesarean section.[12-17] Ofloxacin was no better than doxycycline in eradicating *Mycoplasma hominis* or *Ureaplasma urealyticum* from the lower genital tract in the present study. Based on this data, neither of these agents would be suitable for eradicating either of these cell wall-less bacteria from the endocervix.

Although only three patients in the present study had a coinfection with *N. gonorrhoeae,* the one patient treated with ofloxacin was found to be free of both *C. trachomatis* and *N. gonorrhoeae* on posttherapy evaluation. In other studies containing large numbers of patients ofloxacin was found to be very effective in eradicating *N. gonorrhoeae.*[18-20] The accepted standard of treatment for uncomplicated cervical infection by *N. gonorrhoeae* or *C. trachomatis* is to administer a regimen of antibiotics effective against both of these organisms. The Centers for Disease Control has recommended the administration of 250 mg of ceftriaxone intramuscularly, followed by 100 mg of doxycycline, orally, twice daily for 7 days.[4] The use of ceftriaxone has been advised because of the increasing isolation of *N. gonorrhoeae* strains resistant to penicillin, tetracycline, cefoxitin, or spectinomycin. The national surveillance data revealed that resistant strains of *N. gonorrhoeae* are being isolated across the United States.[2] Because antimicrobial-resistant strains of *N. gonorrhoeae* are becoming widespread, with approximately 21% of strains being resistant to penicillin, tetracycline, cefoxitin, or spectinomycin, and because *C. trachomatis* is frequently found in conjunction with *N. gonorrhoeae,* ofloxacin appears to be a likely alternative and perhaps first-line antibiotic for the treatment of both of these common sexually transmitted organisms. The use of a single antibiotic should be more economic, administration is easier, and there is virtually no concern for resistance since resistance to quinolones is different than that to penicillins and cephalosporins.

Susceptibility of female pelvic pathogens to oral antibiotic agents in patients who develop postpartum endometritis

Mark G. Martens, MD, Sebastian Faro, MD, PhD, Maurizio Maccato, MD, Gerald Riddle, MS, and Hunter A. Hammill, MD

Houston, Texas

Fifteen hundred patients were enrolled in a prospective, randomized study on the effect of antibiotic prophylaxis during cesarean section. Two hundred thirty-one patients developed postpartum endometritis, and the isolates obtained from the endometrium were tested for sensitivity to ampicillin, cefuroxime, ofloxacin, ciprofloxacin, and clindamycin. Minimum inhibitory concentrations of 50% and 90% of ampicillin, cefuroxime, and clindamycin were similar to previously reported values; however, slight differences were noted in the activity of the two quinolones to common pelvic isolates. The minimum inhibitory concentrations of 90% of ofloxacin and ciprofloxacin to 119 isolates of *Enterococcus faecalis* were 4.0 and 2.0, to 17 isolates of *Staphylococcus aureus* 1.0 and 0.5, to 39 isolates of *Escherichia coli* 0.5 and 1.0, to 46 isolates of *Bacteroides bivius* 4.0 and 8.0, to 57 isolates of *Gardnerella vaginalis* 1.0 and 2.0, to 71 isolates of *Staphylococcus epidermidis* 0.5 and 0.5, to 16 isolates of *Proteus mirabilis* 0.25 and 0.12, and to 50 isolates of *Lactobacillus* species 32.0 and 8.0 μg/ml, respectively. In summary, the quinolones have activity comparable with a variety of other oral agents versus female pelvic pathogens, with the quinolones ofloxacin and ciprofloxacin having better activity against most of the gram-negative isolates. Anaerobic activities were comparable with the β-lactams, but inferior to clindamycin and metronidazole as expected. (AM J OBSTET GYNECOL 1991;164:1383-6.)

Associated with the rising number of cesarean sections being performed is a corresponding increase in the number of women developing postpartum endometritis.[1] Investigations that have studied the microbiology of endometritis have demonstrated that mul-

B. fragilis	4	2

tiple bacterial species are often involved, with a mean number of two to four aerobic and anaerobic organisms recovered from each patient.[2]

In an effort to treat these polymicrobial infections, physicians have often relied on a combination of parenteral agents, such as clindamycin plus an aminoglycoside.[2] Single-agent alternatives, such as cefoxitin, ceftizoxime, mezlocillin, and piperacillin, have been used successfully.[3-5] Although most of these infections respond to parenteral agents alone, exact oral equivalents are often unavailable for patients who require extended therapy (such as patients with bacteremia, those with limited intravenous access, or those with abscesses).

This investigation examines the susceptibilities to several oral agents of organisms isolated from the endometrium of patients with endometritis after cesarean section. The newer oral antibiotics may provide a more economic alternative to parenterally administered agents where indicated.

Material and methods

Fifteen hundred patients were enrolled in a prospective randomized study on the effects of antibiotic prophylaxis with several β-lactam regimens during cesarean section. Eighty percent of the patients received a cephalosporin regimen, and 20% received a penicillin class agent as prophylaxis. At the time of diagnosis of postpartum endometritis, endometrial cultures were obtained by placement of a sterile speculum into the vagina, and the cervix was cleansed with a povidone iodine solution. The cervix was gently dilated, and an endometrial suction device (Pipelle, Unimar, Wilton, Conn.) was placed in the endometrial cavity to the uterine fundus. The tissue sample removed was placed into anaerobic transport agar (BBL, Cockeysville, Md.). All three specimens were cultured for aerobic and anaerobic organisms as well as *Mycoplasma, Ureaplasma,* and *Chlamydia* species with routine techniques as described previously.[6] Susceptibility testing was performed by microtube dilution methods (BBL Sceptor, Towson, Md.), and percent susceptibility was determined by minimum inhibitory concentration (MIC) interpretive standards from the National Committee for Clinical Laboratory Standards.[7]

Results

Two hundred thirty-one of the 1500 patients enrolled (15.4%) developed evidence of postpartum endometritis. Four hundred thirty-eight isolates were isolated for an average of 1.9 aerobic or anaerobic isolates per patient. *Enterococcus faecalis* was the most common gram-positive isolate and was isolated in 119 patients (52%). *Gardnerella vaginalis* was the most common gram-negative isolate and was found in 57 patients (25%). *Bacteroides bivius* was the most common anaerobic isolate and was present in 46 (20%) of patients diagnosed with endometritis. The remainder of the isolates are listed in Table I.

The MICs of 50% and 90%, MIC_{50} and MIC_{90}, respectively, are listed in Tables II through IV. Because the human pharmacokinetics of the tested antibiotics vary greatly, dosing regimens and achievable serum levels are also quite varied. To compare the activity of various antibiotics versus a specific pathogen, the MICs are used to create a percentage susceptibility table. Table V combines both the percentage susceptible and those designated as moderately susceptible.

Comment

Postpartum endometritis represents one of the most common pelvic infections. Soft tissue infections of the female genital tract are the result of upper genital tract inoculation from the cervicovaginal flora. Therefore lower genital tract organisms, such as *E. faecalis, G. vaginalis,* and *B. bivius,* become frequent pathogens in infections such as endometritis. The preponderance of the gram-positive isolates and non-fragilis strains of *Bacteroides* is consistent with most recent investigations of postoperative bacteriology in patients receiving β-lactam prophylaxis.[2,3,6] Because of the polymicrobial nature of pelvic infections, therapy is often initiated with a combination of antibiotics such as clindamycin or metronidazole plus an aminoglycoside or a broad-spectrum single agent. Although these infections are frequently eliminated with these intravenous agents without the need for follow-up oral antibiotics, oral agents may sometimes be indicated or necessary for patients with limited intravenous access or those tolerating oral nourishment and complicated infections requiring prolonged therapy such as bacteremia, ab-

scess, phlegmon formation, septic pelvic thrombophlebitis, and pyelonephritis.

Oral equivalents for the aminoglycoside-containing regimens are not readily available. Agents comparable with the parenteral β-lactam agents are unavailable, with the possible exception of amoxicillin-clavulanic acid. Therefore the choice of an oral agent should be based on matching its spectrum of activity with the presumed or isolated pelvic pathogen or pathogens. From the direct culturing of the endometrium in patients diagnosed with endometritis after cesarean, it appears that the following organisms are most frequently isolated: *E. faecalis, G. vaginalis, B. bivius,* and *Escherichia coli.* In addition, coverage should also be provided for *Streptococcus agalactiae.*

According to the susceptibility testing of these isolates, coverage of these organisms with ampicillin is poor in many areas including the *Enterobacteriaceae,* the anaerobes, and *Staphylococcus* species. Therefore its use should be limited to enterococcal infections and isolates tested as susceptible.

Clindamycin and metronidazole had excellent activity against anaerobes as expected; however, metronidazole has little aerobic coverage, and thus it was not tested against aerobic organisms. Clindamycin demonstrated good activity against gram-positive organisms except for the enterococci, but has little gram-negative activity.

Cefuroxime axetil, a new oral second-generation cephalosporin, is the oral equivalent to intravenous cefuroxime. Its good gram-negative activity may make it an appropriate oral agent in gram-negative infections

such as pyelonephritis or soft tissue infections with susceptible organisms, especially in pregnant patients in whom the quinolones are contraindicated.

Of all the agents tested, the quinolones—ofloxacin and ciprofloxacin—demonstrated the broadest range of activity. Their gram-negative activity was superior to all other agents, with the activity of ofloxacin and ciprofloxacin essentially equivalent. The gram-positive activity was also excellent; however, there was slightly better activity by ampicillin versus the enterococci. Although activity was much poorer for the quinolones against the lactobacilli, this still may be beneficial; Faro et al.[8] have described the protective benefits of the lactobacilli in maintaining a balanced flora.

The quinolones had only moderate activity versus the anaerobes; ofloxacin maintained a distinct advantage over ciprofloxacin, with 75% and 39% susceptibility for *B. fragilis* and *B. bivius* for ofloxacin, and only 50% and 2% susceptibility with ciprofloxacin. However, only

Table V. Percent susceptible

B. bivius were found with enough frequency to make strong comparisons. In documented anaerobic infections, though, the bulk of the previous literature still suggests the use of clindamycin or metronidazole.

In summary, the quinolone class of antibiotics, ofloxacin and ciprofloxacin, demonstrated a broader range of activity versus female genital tract isolates over the previously studied oral antibiotics ampicillin, cefuroxime, clindamycin, and metronidazole. Although investigations need to be performed to ascertain if use of the oral quinolones can replace empiric intravenous therapy of female genital tract infections, their use in areas in which oral therapy is currently used is supported by their in vitro activity versus common organisms such as *E. faecalis, B. bivius, G. vaginalis,* and *E. coli.*

New directions in the diagnosis and therapy of urinary tract infections

Robert D. Powers, MD
Charlottesville, Virginia

Urinary tract infections are among the most common bacterial infections. To provide appropriate and cost-effective treatment, physicians need to stratify patients with urinary complaints into uncomplicated or complicated categories. This can be accomplished by the history, presenting symptoms, risk factors, and physical examination. Complicated urinary tract infections occur in patients with a history of recurrent infections, signs or symptoms of upper tract disease, or coexisting conditions such as pregnancy, immunosuppression, or structural anomalies of the urinary tract. Uncomplicated urinary tract infections occur in otherwise healthy women who have a history of lower tract symptoms of short duration. Symptoms of urinary tract infection include some combination of dysuria, frequency, urgency, hematuria, and suprapubic pain. An uncomplicated urinary tract infection is not accompanied by fever or flank pain. The microbiology of uncomplicated urinary tract infection is predictable, with *Escherichia coli* and other *Enterobacteriaceae, Staphylococcus saprophyticus,* and *Enterococcus* causing more than 90% of urinary tract infections. A history, brief physical examination, and urinalysis are all that is necessary to diagnose a urinary tract infection. Some of the specialized dipsticks and rapid screens are as accurate as microscopic examination in detecting urine white cells. A presumptive diagnosis can be made when a patient has clinical symptoms and some combination of pyuria, hematuria, or bacteriuria. Urine cultures are unnecessary in uncomplicated urinary tract infections and add substantially to the cost of therapy. Pitfalls in the diagnosis include other entities causing dysuria, such as vaginitis, vulvar lesions, physical or chemical irritants, and sexually transmitted diseases. Appropriate therapy requires selection of a drug and determination of the length of treatment. A minor infection should be treated with easy, safe, cost-effective therapy. For urinary tract infections, there are too many antibiotic options, ranging from a single, parenteral dose to a 14-day course of oral medication. Early optimism about single-dose oral therapy has been replaced by evidence suggesting that 3 days of therapy is probably the best. This will eradicate simple urinary tract infections in virtually all patients and decrease the incidence of relapse, whereas patients who are treatment failures usually have occult upper tract infection. Drug choices for short-course therapy include representatives from the penicillin, sulfa, and quinolone families. Selection of a specific drug requires consideration of costs, allergies, side effects, and spectrum of activity. A knowledge of local microbial sensitivity profiles and individual patient tolerance is helpful in guiding the clinician to the appropriate therapeutic regimen. (Am J Obstet Gynecol 1991;164:1387-9.)

Key words: Urinary tract infection, urethritis, vaginitis, dysuria

Urinary tract infections (UTIs) are among the most common bacterial illnesses seen by physicians. They affect 10% to 20% of women in the United States annually and prompt 5.2 million office visits per year. Total annual U.S. health care expenditures for outpatients with UTIs approach 1 billion dollars; additional millions are spent on the 100,000 patients hospitalized with UTIs yearly.

It is important for the physician in clinical practice to have a rapid, cost-effective, yet comprehensive approach to female patients with urinary tract complaints. Accurate diagnosis leads to appropriate therapy, which typically involves the administration of oral antimicrobial agents. Numerous effective drugs are available for the treatment of UTIs, and thus the clinician must have an effective way of narrowing the options for each patient. During the past few years, research into appropriate diagnostic and therapeutic regimens has simplified the approach to UTIs by doing away with some time-honored practices.

Approach to the patient with a UTI

Women with UTIs typically have dysuria. Because dysuria has a number of origins (Table I), the initial history and physical examination should be directed at defining the source of the complaint. In addition to UTI, other disorders of the urethra, vagina, and perineum must be considered in the evaluation of women with dysuria. Usually the urinary tract can be isolated as the source of dysuria by taking a careful history. If

Table I. Causes of dysuria

UTI: Lower or upper tract
Urethritis: *Chlamydia*, gonorrhea, herpesvirus
Vaginitis: Bacterial vaginosis, *Trichomonas*, yeast
Perineal lesions: herpesvirus, other sexually transmitted diseases, dermatologic diseases
Physical or chemical irritants: Diet, occupational exposures

there are inconsistent or confusing historical features, examination of the perineum and pelvic organs is essential for accurate diagnosis.

Once it has been established that the dysuria originates in the urinary tract, the next step is to make the distinction between complicated and uncomplicated infection. Uncomplicated UTI (or acute cystitis) is a bacterial infection of the bladder occurring in an otherwise healthy woman. These patients generally have a short duration of symptoms, including some combination of dysuria, frequency, urgency, hematuria, and suprapubic pain or tenderness. Signs and symptoms of UTI (fever, flank pain, or tenderness) are absent. Patients with signs and symptoms of UTI, or those who are immunocompromised are considered to have complicated UTIs. Men, pregnant women, and those with recurrent infections or structural or functional anomalies of the urinary tract also fall into the complicated UTI category.

Patients with complicated UTIs require urine culture and sensitivity determinations and a longer, more aggressive course of treatment. Although hospitalization is not always necessary, close follow-up is essential in these patients to prevent morbidity associated with invasive infection. In addition to a 7- to 10-day course of an appropriate oral antimicrobial agent, "sequential" therapy may be indicated. This involves initial treatment with a parenteral dose of gentamicin or ceftriaxone before the initiation of outpatient therapy. Conversely, uncomplicated UTIs can be treated effectively with a short course of oral antimicrobial agents, and usually do not require much in the way of laboratory evaluation.

Laboratory test use in UTI

In a patient who appears by history and physical examination criteria to have an uncomplicated UTI, a urinalysis is all that is necessary for laboratory confirmation of the diagnosis. Examination of spun urine should disclose numerous white blood cells and bacteria. The newer dipsticks that test for leukocyte esterase and nitrite may substitute for a urinalysis if interpreted correctly. When the results of a dipstick test are positive for both leukocyte esterase and nitrite in the appropriate clinical setting, a microscopic examination of the urine is probably unnecessary. Blood tests such as a complete blood count are costly and are not helpful in the diagnosis or therapy of uncomplicated UTI.

Table II. When urine culture is appropriate

Complicated UTIs
Uncertain clinical or urinalysis features
Relapse
Recent hospitalization or invasive procedure

Whether to culture a urine specimen in a patient with a UTI is an important consideration given the cost/benefit ratio. The cost to the patient for a urine culture with sensitivities is about $40, and in many cases results will become available long after the patient is cured. Accordingly, urine culture is not recommended for most patients with uncomplicated UTI but should be reserved for those patients (Table II) in whom the situation is complicated or confusing. Despite the classic teaching that 10^5 colony forming units per milliliter are necessary for a positive urine culture, recent evidence indicates that a true positive culture can have as low as 100 colony forming units per milliliter of bacteria.

Treatment of UTI

Once the diagnosis of UTI has been established and the patient is assigned to either the complicated or uncomplicated category, the choice of an antimicrobial agent must be made. Because most UTIs will be treated empirically, a knowledge of the likely pathogens is necessary to guide selection of appropriate therapy. Most UTIs are caused by species of gram-negative rods (Table III), with about 10% caused by *Enterococcus* or *Staphylococcus saprophyticus*. There may be regional or local variations to this list, and it is important for clinicians to know their community profile of causative organisms and their sensitivities. This information is available from hospital or commercial microbiology laboratories. The goal of therapy for UTI is to eradicate the infecting organism while causing minimal systemic or local side effects. Allergic reactions are a concern, as are the development of yeast vaginitis or selection of resistant flora in the gastrointestinal tract. For a regimen to be effective in large numbers of patients, it should be low cost and have a convenient dosage schedule.

Numerous antimicrobial agents are appropriate for oral therapy of UTIs (Table IV). Most of the common pathogens are sensitive to sulfa derivatives and cephalosporins. Ampicillin and amoxicillin are no longer considered optimal choices because of a 20% to 30% resistance in *Escherichia coli*.

The principal new development in the treatment of UTIs is the release of the quinolone class of antibiotics. These nalidixic acid derivatives have excellent activity against a broad range of urinary tract pathogens, and the drugs are well tolerated by patients. Norfloxacin, ofloxacin, and ciprofloxacin are presently available; norfloxacin is approved only for UTIs since it is heavily concentrated in the urine. Ciprofloxacin and ofloxacin are effective against a wide variety of bacterial infec-

Table III. Microbiology of UTIs

80% *E. coli*
10% *Klebsiella* sp, *Proteus* sp, *Enterobacter* sp, *Pseudomonas* sp
10% Gram-positive: *S. saprophyticus, Enterococcus*
Note: Culture positive 10^2-10^5 CFU/ml

tions, including those involving the urinary tract. Numerous other quinolone compounds are in various stages of development. The principal advantage they offer over more conventional agents for UTIs is increased activity against *Pseudomonas* species.

At present trimethoprim/sulfamethoxazole is probably the best combination of efficacy and cost for treatment of uncomplicated UTIs. The quinolones, cephalexin, and nitrofurantoin offer excellent alternatives when allergy, patient preferences, or past failures are important. These agents have excellent clinical efficacy but are two to three times more expensive than trimethoprim/sulfamethoxazole.

Duration of antibiotic therapy is an important consideration in UTI. The classic teaching that a 7- to 10-day course is necessary has largely been abandoned, and these long courses should be reserved for patients with complicated UTI or failure of a shorter regimen. Initial optimism about the use of single-dose therapy has been tempered by an unacceptable failure rate in certain populations. As such, a short course of 3 to 5 days is advisable for the great majority of women with uncomplicated UTIs. Trimethoprim/sulfamethoxazole, ciprofloxacin, and norfloxacin can be given twice-daily for short course treatment. Ofloxacin may offer once-daily therapy for short-course treatment of uncomplicated UTIs because of its extended half-life and increased serum and urine levels.

Follow-up of patients with uncomplicated UTIs should be symptom driven. In a private office practice, the cure rate for short-course therapy of uncomplicated UTI should approach 90%. Some patients who failed to respond to therapy have occult upper tract UTIs and must be treated with a longer course tailored to the infecting organism. Noncompliant patients or those with a resistant organism will have recurrent or persistent symptoms and merit further diagnostic analysis.

Summary

Women with UTIs can be stratified into uncomplicated or complicated groups by simple historical and physical examination criteria. Those patients with complicated UTIs require a combination of parenteral and oral therapy or a prolonged (7 to 14 days) course of oral antimicrobial agents. Uncomplicated cystitis can be treated with 3 to 5 days of inexpensive, well-tolerated antibiotics, giving a very high cure rate. Of the agents currently available, trimethoprim/sulfamethoxazole probably offers the best combination of efficacy and cost-effectiveness. Quinolones provide an expanded field of alternatives for the safe and effective treatment of all types of UTI. Looking ahead into the 1990s, the recent release of ofloxacin and the expected approval of other compounds will increase the number of quinolone agents available for clinical use. Ultimately, a variety of quinolones will be available, giving clinicians a broader range of effective compounds from which to choose. Individual differences in antimicrobial spectrum and pharmacokinetics will distinguish the quinolones from one another, and the variety will better enable physicians to tailor therapy to a specific clinical situation.

A randomized trial of ofloxacin versus cefoxitin and doxycycline in the outpatient treatment of acute salpingitis

George D. Wendel, Jr., MD, Susan M. Cox, MD, Roger E. Bawdon, PhD, Sheri K. Theriot, RNC, Molly C. Heard, MA, and Brenda J. Nobles

Dallas, Texas

The object of this randomized study was to compare the safety and efficacy of oral ofloxacin, 400 mg twice daily for 10 days, versus intramuscular cefoxitin, 2 gm, plus oral probenecid, 1 gm, followed by oral doxycycline, 100 mg twice daily for 10 days, in the outpatient treatment of uncomplicated acute salpingitis. Thirty-eight women (53%) had *Neisseria gonorrhoeae* from their pretreatment endocervical or endometrial cultures, and 18 had *Chlamydia trachomatis* (25%). Thirty-five of 37 women (95%) treated with the ofloxacin regimen were clinically cured, and 34 of 35 (97%) were cured with the cefoxitin-doxycycline regimen ($p = 0.52$). One clinical failure occurred in each group with *N. gonorrhoeae* infection, and one failure occurred in the ofloxacin group because of side effects. The bacteriologic response for *N. gonorrhoeae* in both groups was 100%. The eradication of *C. trachomatis* was 100% (10/10) for the cefoxitin/doxycycline group and 86% (6/7) for ofloxacin. The side effects were similar in both groups of subjects. In this study both regimens were effective for the outpatient treatment of uncomplicated acute salpingitis. (Am J Obstet Gynecol 1991;164:1390-6.)

Key words: Ofloxacin, acute salpingitis, *N. gonorrhoeae*, *C. trachomatis*

There is no single, oral agent with adequate efficacy in the treatment of acute salpingitis,[1, 2] a polymicrobial infection most commonly caused by *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, and other aerobic and anaerobic pathogens.[3-5] Although many patients are hospitalized for treatment, most women are treated for acute salpingitis as outpatients.[6] Patients with mild or uncomplicated salpingitis (without diffuse peritonitis or pelvic abscess)[7] who are able to tolerate oral medications are generally considered candidates for ambulatory therapy. Prior investigations have revealed the limitations of penicillin plus ampicillin, doxycycline, and tetracycline in the outpatient therapy of acute salpingitis.[2, 8, 9] Current Centers for Disease Control–recommended therapeutic regimens include an agent with broad-spectrum efficacy against *N. gonorrhoeae*, other aerobes, and anaerobes plus an antichlamydial agent.[10] With inpatient therapy these can be administered simultaneously or sequentially. For the outpatient therapy of uncomplicated acute salpingitis, this combination is usually given sequentially: an intramuscular injection of an antigonococcal agent followed by the oral administration of an antichlamydial agent for approximately 10 days.[10]

Typically tetracycline or doxycycline is the oral agent of choice for outpatient treatment of *C. trachomatis* infection.[11] Recently antimicrobials such as amoxicillin and clindamycin have generated renewed interest in their antichlamydial activities.[12, 13] However, none of these agents have satisfactory clinical experience or efficacy to warrant their recommendation as a single agent for therapy of *C. trachomatis*. The newer fluoroquinolones have excellent in vitro sensitivities for a broad spectrum of pathogens, including *N. gonorrhoeae* and *C. trachomatis*.[14, 15] They can be administered orally and may be effective single agents for the treatment of sexually transmitted diseases.[16] Clinical trials have shown clinical and microbiologic responses in 98% to 100% of patients with gonorrhea[17-19] and 83% to 100% of patients with chlamydial infection treated with ofloxacin.[19-21] The purpose of this study was to compare the safety and efficacy of ofloxacin, a new fluorinated 4-quinolone, versus cefoxitin plus probenecid, followed by doxycycline, in the outpatient treatment of uncomplicated acute salpingitis.

Material and methods

This study was a prospective, randomized, open-label phase III clinical trial to evaluate the safety and efficacy of ofloxacin in the treatment of uncomplicated acute salpingitis. The study was approved by the University

From the Department of Obstetrics and Gynecology, University of Texas Southwestern Medical School and Parkland Memorial Hospital.

Supported in part by a grant from Ortho Pharmaceutical Corporation, Raritan, New Jersey.

Table I. Diagnostic inclusion criteria for uncomplicated acute salpingitis

All three of the following:
Direct lower abdominal tenderness with or without rebound tenderness
Cervical motion tenderness
Adnexal tenderness
Plus at least one of the following:
Recent positive endocervical culture for *N. gonorrhoeae* or *C. trachomatis*
Temperature >100.4° F
White blood cell count >10,000/mm³

Table II. Clinical severity score for grading acute salpingitis

The following signs were evaluated:
Lower abdominal direct tenderness
Adnexal tenderness
Pain on motion of cervix or uterus
According to the following grades:

Grade	Score	Discomfort
Severe	3	With minimal pressure
Moderate	2	Easily elicited by observation of facial expression
Minimal	1	Not evident by observation of facial expression
Absent	0	Inability to elicit any abnormal discomfort

Total score is equal to sum of value of each sign.
Maximum score = 9.

of Texas Southwestern Medical Center Institutional Review Board. The subjects were enrolled from the Obstetrics and Gynecology Emergency Room of Parkland Memorial Hospital after they gave informed consent between May 1, 1987, and Dec. 1, 1987.

Nonpregnant, nonlactating women using a reliable form of contraception who met the inclusion criteria for uncomplicated acute salpingitis[7] (Table I) were offered entry into the study. The patients were excluded from the study if their pelvic infection was severe enough to require parenteral antimicrobial therapy (diffuse peritonitis) or if surgical intervention within the next 24 hours was anticipated. In addition, patients were excluded if there was evidence of a pelvic abscess on sonographic or clinical examination.

All the patients were questioned about the duration of symptoms, past history of pelvic inflammatory disease, and possible allergy to study medications. In addition, all patients were given a clinical severity score at the time of admission according to a modification of previously described grading systems for acute salpingitis (Table II).[22, 23] All patients underwent a complete physical examination, and cultures were collected for *N. gonorrhoeae* and *C. trachomatis*. Endocervical cultures for *N. gonorrhoeae* plus *C. trachomatis* and gonococcal rectal cultures were collected on admission to the study. During the first half of the study period, all patients also had endometrial cultures for *N. gonorrhoeae* and *C. trachomatis*. Laboratory evaluation included a complete blood count, platelet count, white blood cell differential count, and erythrocyte sedimentation rate. Serum chemistry tests of renal function and liver function were also obtained as was a prothrombin time and a partial thromboplastin time. A urinalysis and pregnancy test were performed. All patients underwent pelvic sonography to rule out pelvic masses or abscesses before entry into the study.

After informed consent was obtained, subjects were assigned a randomized code number designating therapy, which was then administered in an open fashion. The two treatment regimens were instituted immediately in the emergency room area. An equal number of women was assigned to each treatment regimen. Patients received either ofloxacin, 400 mg orally every 12 hours for 10 days, or cefoxitin, 2 gm intramuscularly, and probenecid, 1 gm orally, followed by doxycycline, 100 mg orally every 12 hours for 10 days. Thus all patients received a 10-day course of outpatient therapy for acute salpingitis.

The subjects were instructed about the nature of their pelvic infection and the need for compliance to the therapeutic regimens. Their sexual partners were referred to the Dallas County Sexually Transmitted Disease Clinic for evaluation and treatment. The patients were instructed to abstain from coitus until completion of the study but were also given nonmedicated, nonlubricated condoms as a precaution. Patients were instructed to report any unprotected coitus at follow-up visits.

The subjects were asked to return for follow-up evaluation 3 to 4 days after entry into the study, at 13 to 15 days after entry into the study, and at 25 to 30 days after entry into the study. At the initial follow-up visit, patients were questioned about compliance and side effects but were not examined unless there were complaints. At the 13- to 15-day visit, endocervical and endometrial cultures for *N. gonorrhoeae* plus *C. trachomatis*, rectal *N. gonorrhoeae* cultures, the clinical severity score, and laboratory tests were repeated. The clinical response to therapy and the microbiologic response for *N. gonorrhoeae* were determined at this visit. At the 25- to 30-day follow-up visit, endocervical, endometrial, and rectal cultures and the clinical severity score were repeated; also, the microbiologic response for subjects with *C. trachomatis* was determined. An effort was made to ensure compliance with all three follow-up visits by telephone contact and registered mail for delinquent patients.

The clinical response compared with the examination at the time of admission of all evaluable patients was determined at the 13- to 15-day follow-up visit. A cure

was defined as complete resolution of tenderness (>65% decrease in clinical score). Clinical improvement was defined as partial resolution of tenderness (31% to 64% decrease in clinical score), and failure was defined as minimal or no improvement in tenderness (<30% decrease in clinical score). A microbiologic cure required eradication of all pathogens present at the time of admission. A microbiologic partial cure was eradication of only one pathogen with persistence of the other. A microbiologic failure was defined as a persistence or relapse of the original pathogen(s).

Cultures were obtained from the endocervical canal for *N. gonorrhoeae* and *C. trachomatis* by means of sterile Dacron applicators after endocervical mucus and pus were removed with a dry sterile swab. Endometrial cultures were obtained by a double-lumen catheter-protected brush (MediTech, Watertown, Mass.). The *N. gonorrhoeae* cultures were immediately plated on modified Thayer-Martin medium and incubated at 35° C in a 5% carbon dioxide environment. Isolates were confirmed by standard microbiologic methods. All the *N. gonorrhoeae* isolates were tested for the presence of β-lactamase by nitrocefin-impregnated disks (Cefinase, BBL Microbiology Systems, Cockeysville, Md.). *C. trachomatis* specimens were obtained after *N. gonorrhoeae* cultures. These specimens were then placed in a sterile transport media (Cultureset, Ortho Diagnostic Systems, Raritan, N.J.). The specimens were then transported to the laboratory within 15 minutes of collection for inoculation into cycloheximide-treated McCoy cells in tissue culture vials or stored at −70° C until cultures could be performed. The tissue cultures were performed according to a previously described protocol.[24]

Susceptibility testing of *N. gonorrhoeae* isolates to the three antimicrobials was performed with agar dilution methods in accordance with approved standards.[25] Bacterial resistance to cefoxitin, doxycycline, and ofloxacin was defined as a minimal inhibitory concentration of ≥16 μ/ml, ≥8 μg/ml, and ≥4 μg/ml, respectively. Susceptibility testing was performed for *C. trachomatis* only if there was a treatment failure.

A retrospective medical record review was performed in all subjects 3 years after the completion of the study to ascertain subsequent pregnancies. The review only included visits or admissions to Parkland Memorial Hospital. Voluntary infertility and sequelae, such as chronic pelvic pain and involuntary infertility, were not measurable.

Categoric data were analyzed for differences in frequency between the two treatment groups by means of χ^2 test. Continuous data were analyzed with a two-tailed Student t test. A p value of <0.05 was considered significant in the data analyses.

Results

Ninety-six women were enrolled in the study for treatment with the two study regimens. Twenty-four women were considered unevaluable because of total noncompliance with the study drug regimen (one woman) or lack of attendance at any follow-up visits (23 women). The evaluable study group consisted of 72 women: 35 who received the cofoxitin-probenecid and doxycycline regimen and 37 who received ofloxacin.

A comparison of the two study groups regarding age, race, marital status, parity, and a prior history of sexually transmitted diseases revealed no significant differences (Table III). A comparison of clinical and laboratory variables at the time of enrollment revealed no significant difference in days of symptoms before admission, temperature, clinical severity score, height, weight, white blood cell count, or erythrocyte sedimentation rate (Table III).

Results of a culture from the endocervix and endo-

metrium (or both) were positive in 63% (45/72) of patients (Table IV). The most common isolate was *N. gonorrhoeae*, which was found in 53% (38/72) of the women. Twenty-five percent (18/72) of the women had *C. trachomatis* from their genital cultures. Ten percent (7/72) of the women had *C. trachomatis* alone, and 15% (11/72) had both *N. gonorrhoeae* and *C. trachomatis* in their cultures. Overall 29% (11/38) of patients with *N. gonorrhoeae* had concomitant *C. trachomatis* infection. No significant differences were noted between the rates of isolation of *N. gonorrhoeae*, *C. trachomatis*, *N. gonorrhoeae* and *C. trachomatis*, or negative cultures when the two study groups were compared.

Forty-three (60%) of evaluable patients had endometrial cultures performed. There was concordance between the endocervical and endometrial cultures in 91% of the subjects (39/43). Three women had positive cervical cultures but no endometrial growth; one woman had only endometrial *C. trachomatis*. Overall 58% (25/43) of the subjects had positive endometrial cultures. Twenty-one (49%) women had gonococcal infection, and five (12%) had chlamydial infection of the upper tract. No significant difference was observed in the rates of upper tract infection between the two study groups.

All but one of the *N. gonorrhoeae* isolates were susceptible to the three study drugs. The strain was resistant only to doxycycline. The minimal inhibitory concentration ranges are shown in Table V. None of the isolates were β-lactamase–producing strains. Susceptibility testing was not performed for any *C. trachomatis* isolates.

Overall 96% (69/72) of patients were clinically cured after they completed the outpatient study regimens. Ninety-five percent (35/37) of the women treated with the ofloxacin regimen were cured, and 97% (34/35) of patients receiving the cefoxitin-probenecid and doxycycline regimen were cured (Table VI). In each group a woman with an endocervical and endometrial infection caused by *N. gonorrhoeae* was considered a clinical failure. One woman in the ofloxacin group with mixed gonococcal and chlamydial endocervical infection was counted as a failure because of side effects. She showed clinical improvement (follow-up severity score of 1 and negative cultures for *N. gonorrhoeae* and *C. trachomatis*) but severe nausea and vomiting after 3 days of treatment. The average clinical severity score at the 13- to 15-day visit in each group was 0.3, and the white blood cell counts were within the normal range for both groups.

Table VII. Clinical response in women with endocervical and endometrial cultures

Site of positive culture	*Cefoxitin-doxycycline*	*Ofloxacin*	*Total*
Endocervix	9/9	11/11	20/20
Endometrium	10/11	11/12	21/23
TOTAL	19/20	22/23	41/43

The response in women with gonococcal infection was 94% (15/16) for cefoxitin-doxycycline and 91% (20/22) for ofloxacin. The response in women with chlamydial infection was 100% (10/10) for cefoxitin-doxycycline and 88% (7/8) for ofloxacin. No significant difference in the clinical cure rate was seen in the group with positive endometrial cultures versus those with only positive endocervical cultures for the individual study groups (Table VII). No patient with only chlamydial infection or culture-negative infection was considered a failure.

The microbiologic response for *N. gonorrhoeae* and *C. trachomatis* is shown in Table VI. No woman had persistence of *N. gonorrhoeae* or *C. trachomatis* at the 13- to 15-day follow-up visit. Despite clinical failure in two women with gonococcal endocervical and endometrial infection and one with mixed endocervical infection, microbiologic eradication of the pathogens present at the time of admission occurred in each case.

Table VIII. Side effects in study groups

	Cefoxitin-doxycycline (N = 35)	*Ofloxacin (N = 37)*
Nausea	3	2
Thrombocytosis	2	0
Candida vaginitis	2	1
Eosinophilia	2	1
Monocytosis	1	0
Headaches	0	1
Allergy	0	1
TOTAL	9 (26%)	6* (16%)

*p = NS.

At the final follow-up visit at 25 to 30 days after entry into the study, one woman in the ofloxacin group had recurrent *C. trachomatis* and *N. gonorrhoeae* (Table VII). The subject had been clinically and microbiologically cured at her prior visit, and she admitted to unprotected coitus with untreated partners since the prior follow-up visit. She had a normal pelvic examination, free of signs of clinical pelvic infection or cervicitis. The minimal inhibitory concentrations for the recurrent *N. gonorrhoeae* isolates were identical to the strain from admission to the study. All the study subjects maintained normal clinical examinations at the final follow-up visit.

Nine percent (6/64) of the women had rectal *N. gonorrhoeae* infection, and eight women did not have rectal cultures taken. The three women in each treatment group resulted in a concomitant rectal infection rate of 16% (6/38) in those with *N. gonorrhoeae*. There were no treatment failures in either group at the 13- to 15-day follow-up.

Twenty-one percent (15/72) of patients developed side effects during treatment. Twenty-six percent (9/35) of patients treated with cefoxitin-probenecid followed by doxycycline developed side effects, and 16% (6/37) treated with the ofloxacin regimen developed side effects. There were no significant differences in the frequency of side effects in the two groups or in the type of side effects noted (Table VIII). One patient in the ofloxacin group developed severe nausea and vomiting early in therapy and was removed from the protocol. She was switched to a parenteral regimen as an inpatient and was considered a treatment failure because of side effects in the previous efficacy analysis.

Retrospective medical record review revealed that 87% (63/72) of the women had subsequent visits or admissions to Parkland Memorial Hospital. Eight women in the cefoxitin-doxycycline group and nine women in the ofloxacin group had prior tubal ligations; they were omitted from analysis. Intrauterine pregnancies occurred in 33% (9/27) of the subjects in the cefoxitin-doxycycline group and in 54% (15/28) of the ofloxacin group (p = 0.09). One additional ectopic pregnancy occurred in the ofloxacin group. Crude pregnancy rates were not adjusted for prior salpingitis, subsequent recurrent salpingitis, or voluntary infertility.

Comment

The antimicrobial regimens compared were equally effective in the outpatient treatment of women with uncomplicated pelvic inflammatory disease. Excellent clinical and bacteriologic efficacy were noted with both regimens in this group of patients. The clinical efficacy of both regimens was similar for patients with *N. gonorrhoeae* and *C. trachomatis* infection (or both), as well as for patients who had neither pathogen isolated. Because of the number of subjects evaluated and subsequent low statistical power, significant differences between the two regimens may have been obscured. The efficacy of therapy may also be related to the preselection of patients with mild or uncomplicated pelvic infection, excluding those patients with tuboovarian abscesses or diffuse peritonitis.[7] Such patients are treated best by inpatient parenteral therapy and would be inappropriate candidates for outpatient therapy.

A limitation of this study is that the diagnosis of salpingitis was made by a combination of clinical signs and symptoms (Table I).[22, 23] Unfortunately, the laparoscopic confirmation of the diagnosis of acute salpingitis may occur only in 65% of patients who meet similar clinical criteria.[26] Supportive of the correct diagnosis is the fact that 63% of the subjects had a pathogen isolated from their endocervix and endometrium (or both) commonly associated with acute salpingitis, either *N. gonorrhoeae* or *C. trachomatis*. In addition, 58% of the women had these pathogens isolated from endometrial cultures. Sweet[27] had reported a similar frequency (53%) of upper tract infection with *N. gonorrhoeae* and *C. trachomatis* in 188 women with acute pelvic inflammatory disease.

The criteria used were developed to select women with mild or uncomplicated acute salpingitis, free of severe toxicity, pelvic abscesses or diffuse peritonitis, who would be acceptable candidates for ambulatory therapy, In addition, selecting women with mild acute salpingitis would tend to enroll more subjects with pelvic infection caused by *C. trachomatis*, who often have relatively benign clinical examinations compared with women with gonococcal or nongonococcal, nonchlamydial salpingitis.[28]

Overall the microbiologic response for *N. gonorrhoeae* and *C. trachomatis* was excellent. At days 13 to 15, the gonococcal microbiological response was 100% in both groups. None of the patients in either study group had evidence of a persistent chlamydial infection during the study. One patient in the ofloxacin group had a recurrent gonococcal and chlamydial infection at the 25- to

30-day visit. Although this may be a microbiologic failure, it is more likely a reinfection from an acknowledged untreated sexual partner rather than a relapse.

Despite the clinical and microbiologic evidence of response to the therapeutic regimens administered, questions could arise about adequacy of the complete eradication of a nongonococcal, nonchlamydial infection of the upper genital tract. This issue is of concern because of the limited in vitro activity of ofloxacin and other quinolones against anaerobic bacteria. In one salpingitis study ciprofloxacin failed to eradicate bacterial-vaginosis–associated organisms of the upper genital tract from posttreatment endometrial cultures in women despite excellent clinical response.[29] Whether such persistence of organisms portends a greater risk for infertility, ectopic pregnancy, and other sequelae of salpingitis is unclear.

All the subjects judged to be clinically cured had normal clinical severity scores (value 0 or 1) at their second and third follow-up visits, and their temperature and white blood cell counts returned to within the normal range. These markers are indirect assessments of response to infection and cannot substitute for laparoscopically confirmed[27] response of infection, which was not used in this study. Follow-up of subjects 3 years later demonstrated pregnancies in 54% of the women treated with ofloxacin and in 33% of those in the cefoxitin-doxycycline group. These rates represent a minimum, since the survey was a retrospective, passive medical record review of one institution without correction for voluntary infertility or lack of further contact. The crude rate of intrauterine pregnancy (uncorrected for prior or subsequent salpingitis) for the ofloxacin group is similar to the rate of 63% observed in Westrom[30] in a series of 415 women with previous pelvic inflammatory disease.

In this study a regimen of oral ofloxacin, 400 mg twice daily for 10 days, was of equal efficacy to a regimen of intramuscular cefoxitin, 2 gm, plus oral probenecid, 1 gm, followed by oral doxycycline, 100 mg twice a day for 10 days, in treating patients with uncomplicated acute salpingitis. Both regimens had clinical efficacy of 95% or greater, with eradication of *N. gonorrhoeae* and *C. trachomatis* in every evaluable patient except in one woman who may have been reinfected by an untreated sexual partner. Significant side effects in both groups were mild and similar in nature, with only one severe episode requiring discontinuation of the medication. Although the number of subjects in this study does not permit firm conclusions regarding the equivalence of the two regimens, 400 mg of oral ofloxacin given every 12 hours for 10 days is a promising single-agent treatment for uncomplicated acute salpingitis. If these results are confirmed in larger series, particularly in women with chlamydial infection, single-agent therapy with ofloxacin may offer an acceptable alternative to combination therapy for the outpatient treatment of uncomplicated acute salpingitis.

The clinical experience with ofloxacin in the treatment of sexually transmitted diseases

Michael L. Corrado, MD
Raritan, New Jersey

Sexually transmitted diseases are an important cause of morbidity in women. Some of the common causes of sexually transmitted disease include *Neisseria gonorrhoeae, Chlamydia trachomatis,* and in some patients *Ureaplasma urealyticum. N. gonorrhoeae* has become more resistant to traditional therapies including penicillin. Resistance to penicillin is mediated by the elaboration of β-lactamase for most organisms and by chromosomal resistance in others. Resistance to tetracycline and spectinomycin has been clearly identified, as has an increase in the minimum inhibitory concentrations to some cephalosporins. Because of the potential for concomitant infection with *N. gonorrhoeae* and *C. trachomatis,* many patients are currently treated with a combination of a single dose of ceftriaxone plus a tetracycline for 7 days. Therefore it is significant that a single agent, ofloxacin, has been introduced recently for the treatment of such mixed infections. It also has the potential for treating *N. gonorrhoeae* resistant to other drugs. (AM J OBSTET GYNECOL 1991;164:1396-9.)

Key words: *N. gonorrhoeae, C. trachomatis,* sexually transmitted diseases, urethritis

In this article we review data from clinical trials conducted in the United States between 1984 and 1988. These data represent a compilation across several multicenter trials, all of which were conducted by the Robert Wood Johnson Pharmaceutical Research Institute. In addition, the world literature from February 1983 to February 1990 will be reviewed.

Cervicitis

Ofloxacin was used in the treatment of women with cervicitis. In one study in which ofloxacin was compared with doxycycline, 344 women were enrolled. The regimens included ofloxacin, 300 mg twice daily, versus doxycycline, 100 mg, twice daily, both given for 7 days. In that study a similar percentage of patients receiving ofloxacin had *Neisseria gonorrhoeae* eradicated from various sites as was eradicated with doxycycline (Table I). It is important to note that patients with cervicitis may have simultaneous infection at multiple sites including the anus and pharynx, and as seen in this study, a 7-day course of ofloxacin was effective in eradicating

Table I. Eradication rates of *N. gonorrhoeae* by site*

Site	Regimen		
	Ofloxacin, 300 mg, bid, × 7 days	*Doxycycline, 100 mg, bid, × 7 days*	*Ofloxacin, 400 mg, single dose*
Urethra	1/1	—	10/10
Pharynx	10/10	5/6	8/8
Anus	10/10	11/11	20/20
Cervix	52/53	37/40	90/90

*Studies conducted by and on file at the Robert Wood Johnson Pharmaceutical Research Institute.

N. gonorrhoeae from all patients and all sites with the exception of a single patient in whom the organism persisted in the cervix. In addition, 45 patients who received ofloxacin had concomitant infection with *Chlamydia trachomatis.* Forty-four of 45 patients had their chlamydia infection eradicated. This compares with 39 of 40 patients receiving doxycycline who had the pathogens eradicated. Several other trials involving patients with gonorrhea were conducted in the United States in which the efficacy of ofloxacin was investigated. A total of 1172 isolates of *N. gonorrhoeae* were identified from all clinical trials conducted in the United States. All isolates of *N. gonorrhoeae* were susceptible to ofloxacin. Ninety-nine percent of patients receiving ofloxacin had their infections either cured or improved as did 97% of patients who received comparative regimens. Table I further identifies eradication rates for women enrolled in single-dose studies involving ofloxacin for gonococcal disease. As can be noted, all patients with anal and pharyngeal involvement had the organisms eradicated, as did all 90 patients with cervical involvement. When reviewing the eradication rate from trials conducted in men and women with gonococcal and nongonococcal urethritis or cervicitis, virtually idential eradication rates were identified for *Chlamydia* in both ofloxacin- and doxycycline-treated recipients (Table II).

Pelvic inflammatory disease

Studies conducted in women with pelvic inflammatory disease in the United States in which microbiologic identification was confirmed revealed that all 47 women with pelvic inflammatory disease who had gonococcal disease had the pathogens eradicated (Table III). In addition, 19 had chlamydial pathogens identified, and again, all 19 patients had the *Chlamydia* eradicated. In contrast, although all 23 women with gonococcal disease randomized to treatment with cefoxitin plus doxycycline had their pathogens eradicated, 2 of 15 women treated with the doxycycline regimen had persistence of *Chlamydia.*

Table II. Bacterial eradication rates in multiple-dose studies*

	Ofloxacin	*Doxycycline*
Gonococcus	149/155	176/178
Chlamydia	141/147	167/172

*Studies conducted by and on file at the Robert Wood Johnson Pharmaceutical Research Institute.

Table III. Bacterial eradication rates in pelvic inflammatory disease*

	Cefoxitin + doxycycline	*Ofloxacin*
Gonococcus	23/23	47/47
Chlamydia	13/15	19/19

*Studies conducted by and on file at the Robert Wood Johnson Pharmaceutical Research Institute.

The medical literature from trials conducted outside of the United States revealed 37 published reports from 15 countries involving more than 3600 patients (see Bibliography). Doses of ofloxacin ranged from 300 to 600 mg/day either as a single dose or for as long as 7 days. Although clinical cure and improvement rates varied, by and large most patients had eradication rates of 90% or higher. Microbiologic eradication rates were almost always in the 90% range or higher, with the lowest microbiologic eradication rate occurring in studies conducted in Japan, where in one study only 71% of isolates were eradicated.

Comment

Studies conducted in sexually transmitted diseases suggest that ofloxacin retains a high degree of intrinsic activity against penicillin-resistant as well as penicillin-susceptible gonorrhea. In addition, it exerts a high degree of activity against *Chlamydia,* a pathogen that may be either a copathogen or the sole cause of sexually transmitted disease in some patients. Ofloxacin appeared effective at eradicating pathogens from multiple sites including the anus and pharynx as a single dose for gonorrhea and thereby decreases the likelihood of a potential for disseminated gonococcal disease from a noneffectively treated focus. It seems, however, that the treatment of sexually transmitted diseases involving *Chlamydia* with ofloxacin would require the more traditional 7-day course and not single-dose therapy.

The use of ofloxacin in pelvic inflammatory disease appears to be comparable with the combination of cefoxitin plus doxycycline. Thus ofloxacin offers the potential of monotherapy for the treatment of mixed sexually transmitted infections. The published literature also demonstrates that ofloxacin is effective in gonorrhea and chlamydia, and by and large, studies from across countries have delineated the highly reproduc-

ible eradication rates and clinical cure rates seen in the United States. The few exceptions occurred in Japan and Germany, where a lower dose may be implicated in the lower microbiologic eradication rates.

In conclusion, ofloxacin appears to be effective as monotherapy and single-dose therapy for gonococcal disease, as well as when given twice daily for 7 days for the treatment of mixed infection caused by *C. trachomatis* and the gonococcus.

Summary

Sebastian Faro, MD, PhD
Houston, Texas

The quinolones are a unique class of antimicrobial agents in that they affect the cell's capability to reproduce by interfering with deoxyribonucleic acid (DNA) synthesis. The bacterial enzyme DNA gyrase is essential for DNA replication. All organisms contain a group of enzymes known as DNA topoisomerases, to which DNA gyrase belongs. However, only the bacterial DNA gyrase inserts negative supercoils into DNA.

Coiling of bacterial DNA is essential since the bacterial chromosome is composed of double-stranded DNA 1300 μm long, and it must fit into a bacterium whose average size is 2 μm long and 1 μm wide. Thus DNA gyrase or topoisomerase II causes nicks in the double-stranded DNA, producing negative supercoils, and then seals the nicked DNA. The quinolone's ability to affect DNA gyrase, which is found only in the bacterial cell, may explain why these agents can interfere with bacterial DNA synthesis and not mammalian DNA activity.

The progenitor of the quinolones is nalidixic acid with activity limited to gram-negative facultative anaerobes. The quinolones were slow to develop until the introduction of fluorine and piperazine into the basic molecule. The new quinolones were found to be active against gram-positive, gram-negative activity, including *Staphylococcus aureus* and *Pseudomonas aeruginosa*. There are many quinolones, three of which are approved (ciprofloxacin, norfloxacin, and ofloxacin), and some of which are not available: nalidixic acid, flumequine, cinoxacin, oxolinic acid, pipemidic acid, piromidic acid, rosoxacin, enoxacin, fleroxacin, lomefloxacin, amifloxacin, and difloxacin.

The spectrum of activity of the newer quinolones has evolved to a significant degree that these agents are effective for the treatment of a variety of infections. In considering the agents that are currently available, norfloxacin (Noroxin), ciprofloxacin (Cipro), and ofloxacin (Floxin) are effective against gram-negative facultative anaerobes, such as *Pseudomonas, Campylobacter, Citrobacter, Providencia, Hafnia, Escherichia, Klebsiella, Proteus, Serratia,* and *Enterobacter*. These agents are also active against *Haemophilus influenzae, Branhamella (Moraxella), Acinetobacter, Aeromonas,* and *Neisseria gonorrhoeae*.

The new quinolones are less active against the gram-positive aerobes than against the gram-negative aerobes. However, among the gram-positive bacteria, the quinolones are more active against staphylococci than streptococci. Ciprofloxacin and ofloxacin are active against *S. aureus,* coagulase-negative staphylococci, and *Staphylococcus saprophyticus*. Ofloxacin and ciprofloxacin show good activity against *Streptococcus pneumoniae,* β- and nonhemolytic streptococci, β-hemolytic streptococci (Lancefield groups A, B, C, and G), and *Enterococcus,* although ciprofloxacin is more active than ofloxacin against the β- and nonhemolytic streptococcus and *Enterococcus*.

The quinolones are not very active, in general, against *Gardnerella vaginalis* and anaerobes. However, ofloxacin is more active than ciprofloxacin against members of the *Bacteroides fragilis* and *B. melaninogenicus/oralis* groups. Fusobacteria tend to be resistant to ofloxacin and ciprofloxacin, whereas *Mobiluncus* tends to be very sensitive to both of these quinolones. The gram-positive obligate anaerobes tend to be resistant to ofloxacin with peptostreptococci more susceptible to ciprofloxacin. The Clostridia are resistant to both ofloxacin and ciprofloxacin.

Both ofloxacin and ciprofloxacin have activity against *Chlamydia trachomatis*. Neither of these quinolones is particularly active against *Mycoplasma* or *Ureaplasma*.

Thus the quinolones, particularly ofloxacin, have a broad spectrum of activity that makes the antibiotic well suited for the gynecologic patient. The quinolones should not be used in pregnant and breast-feeding patients because of the potential to cause arthropathy in children. However, in the postpartum patient who is not breast feeding, the quinolones may have a role.

Female genital tract infections are either caused by sexually transmitted organisms or the patient's own endogenous microflora of the genital tract. The two most common sexually transmitted bacteria are *N. gonorrhoeae* and *C. trachomatis,* both of which may cause limited or significant soft tissue infection. These two bacteria can cause urethritis, cervicitis, or endometritis, as well as the more serious salpingitis. Early acute salpingitis is most likely caused by *N. gonorrhoeae,* with fewer cases caused by *C. trachomatis.* Ofloxacin is an ideal agent for the treatment of these infections, since a single agent can be used effectively to treat infection caused by both these organisms. This agent is particularly useful, since the β-lactamase–producing and tetracycline-resistant strains of *N. gonorrhoeae* are not resistant to ofloxacin. The concern of polymicrobial nongonococcal, nonchlamydial salpingitis would not be of particular concern in patients with early acute salpingitis.

N. gonorrhoeae is responsible for 60% to 80% of the cases of acute salpingitis in the United States; *C. trachomatis* is responsible for 20% to 25% of the cases. The aerobic and anaerobic bacteria are probably not involved in early acute salpingitis. These bacteria play a significant role in these patients in whom peritonitis and inflammation of the bowel have become a significant part of the infectious process. In these patients use of ofloxacin or another quinolone without the concomitant use of an anaerobic agent would be inappropriate. This distinction might be made by obtaining an endocervical specimen for Gram's stain and rapid monofluorescent antibody testing for the detection of *Chlamydia.*

A Gram's stain that reveals the presence of intracellular diplococci can be taken as presumptive evidence for the presence of *N. gonorrhoeae.* A positive fluorescent antibody for *Chlamydia* can be viewed as indicative of infection. The presence of either or both of these bacteria does not rule out the presence of other bacteria, but it is unlikely. In any event, treatment for salpingitis may be carried out with ofloxacin or a combination of clindamycin or metronidazole plus ofloxacin, thus broad coverage is provided for the anaerobes, and ofloxacin provides good gram-negative and fair gram-positive coverage.

Soft tissue infections, such as postpartum endometritis and pelvic cellulitis after gynecologic surgery, may also be treated by using a combination of clindamycin or metronidazole plus ofloxacin. These combinations also offer the advantage of oral administration. Parenteral ofloxacin is not yet available. The use of these orally administered agents will provide more than adequate tissue levels. Oral administration also allows the patient to continue therapy as an outpatient once the acute symptoms and signs of infection have resolved.

Finally, it is well known that the excellent activity of the quinolones against gram-negative facultative bacteria makes them ideal for the treatment of urinary tract infection. Perhaps these agents should be used in patients who might harbor resistant bacteria, such as those with repeated infection, in the presence of indwelling catheters and exposure to antibiotics.

Thus the quinolones, and ofloxacin in particular, provide the physician with a unique opportunity for the treatment of bacterial infections. The ability to use one agent for the treatment of both *N. gonorrhoeae* and *C. trachomatis* facilitates compliance on the patient's part and reduces cost and therefore may serve as a potential replacement for ceftriaxone and doxycycline. Ofloxacin is an excellent agent for the treatment of urinary tract infections caused by gram-negative facultative anaerobes as well as *S. saprophyticus.* The mechanism of action of the quinolones reduces the potential for significant toxic effects. Adverse reactions to the quinolones are rare and include nausea, vomiting, diarrhea, rash, pruritus, dizziness, headache, and insomnia. The most frequent side effects are gastrointestinal.

Although the quinolones are broad-spectrum agents potentially suited for a variety of infections, the physician must establish the correct microbiologic diagnosis. The physician must understand the spectrum of activity of the quinolones and realize that all quinolones are not equal in their activity against all bacteria. It is important that the patient be reevaluated during therapy to determine if the antibiotic being used is effective and the signs and symptoms of infections are resolving. Patients infected with *N. gonorrhoeae* and/or *C. trachomatis* should be recultured approximately 2 weeks after the completion of therapy to establish that the organism has been eradicated.
